CLINICAL LECTURE ON INJURIES TO THE ELBOW JOINT IN CHILDREN.

By JONATHAN HUTCHINSON, F.R.S.,

Emeritus Professor of Surgery to the London Hospital.

GENTLEMEN,—I have often asked your attention to the fact, that the elbow is almost the only joint which in children is liable to be dislocated from violence. Now and then we see a dislocation at the hip, even in very young subjects, but as regards the shoulder, the knee, the ankle, the wrist, and the finger joints, those of us who have had the largest experience could easily count up all that we have seen. They are exceedingly rare, the cause of their rarity being that, in each, separation of the adjacent epiphysis usually occurs instead. Of this latter accident at the shoulder, the ankle, and the wrist, we see plenty, and at the knee and hip a few; contrary, however, to what is known to obtain at all the other articulations, dislocations at the elbow in young persons, are reputed to be common, more common, I think, than they are in adults. This fact is probably to some extent explained by the circumstance, that in young children the coronoid process is low and imperfectly ossified. It is, of course, in the adult the chief hindrance to dislocation, but in children its cartilaginous tip may easily be crushed down, or possibly detached This explanation, however, does not cover the whole ground. To a large extent, I feel sure that the popular belief as to the frequency of clean dislocations at the elbow in children is a mistake. They are almost all complicated cases, the complication usually being a partial detachment of the lower epiphysis of the humerus. The ossification of the lower end of this bone occurs, as you know, at several separate points. These are, however, pretty much on a level; and whilst it is quite possible for any one portion to be detached alone, it is also quite possible for the whole epiphysis to be cleanly separated from the shaft by a transverse line of detachment, which permits the condyles and epicondyles to pass backwards together with the bones of the forearm. I need not stop to tell you how to distinguish such an injury from a true dislocation, although mistakes constantly occur; they are excusable only by the fact that the swelling is often very great, the child difficult to examine, and anæsthetics usually omitted. I am sure that you will bear me out that cases are very common in which, after the treatment of a case diagnosed as dislocation backwards at the elbow, the joint remains stiff, swollen, and with much apparent thickening of bones for many months afterwards. Other opinions are often sought in such cases, and the surgeon who reduced the dislocation is often discredited. Such cases are almost always examples of displacement of the epiphysis, complete or partial.

I have seen many examples of complete transverse detachment of the whole lower epiphysis, and have had opportunities of demonstrating several to you. Most of them have come to me late, on account of awkward union, but in a certain number I have had an opportunity of examining the state of things immediately after the accident. I show you here a photograph of one which I examined, and had taken within

55038

half-an-hour of the accident and before any swelling had occurred. The boy had fallen from a horse just by the hospital gates, and was carried straight in, when I chanced to be in the receiving-room. Another such I saw at Stratford, with Mr. John Kennedy. I was visiting another patient with him, when he was hastily called to a little girl of twelve, who had fallen from an apple tree. We went together, gave ether, and had a capital opportunity for examining the points of a most marked example of transverse separation. It was not difficult to get the bone into place, but almost impossible to keep it there. We put it up in a moulded back splint, in which, as in a trough, the elbow rested. Not long after this case, a son of Sir John C., of Sittingbourne, was brought to me for stiffness of elbow, a month after a dislocation. It curiously happened that two years previously I had excised one of his knee joints. He had now fallen down stairs, and, instead of breaking his anchylosed lower limb, had displaced the epiphysis of one elbow. Union had occurred, with much displacement backwards still remaining. The swelling had pretty much disappeared, and the outline of the lower end of the bone was easily distinguished. The elbow was at an obtuse angle, and its area of flexion very limited. I had not sufficient hope of being able to keep it in place to lead me to advise forcible retraction, and we contented ourselves with instituting freer movements. Much improvement has during the subsequent year taken place, and the power of flexion is still far from complete.

Partial separations of the epiphysis are, however, very much more common than complete ones, and much more difficult of diagnosis. Any part of the epiphysis may give way, the central part or either of the condyles. In some cases, in addition to the separation at some part of the epiphysal area there is an oblique fracture of the shaft. You must be prepared for all kinds of complication. It would serve little purpose for me to attempt to describe the symptoms of each variety, a few general rules will serve a better purpose. But then, if there is any obscurity about the case, you may feel sure that the epiphysis is damaged—an uncomplicated dislocation is easy to recognise, easy to reduce, and not very difficult to keep in place. In adults, we all know that dislocations at the elbow are reduced and get quickly well without any stiffness. In children, how different is the prospect! In nearly all cases in them, the elbow remains more or less restricted in its movements. The cause of restriction of movement is not alone the persisting mal-position of fragments, although that accounts for much, it is to be explained in large part by the fact that in such injuries the periosteum is always much stripped up, and that this leads to extensive deposit of new bone. After a while, however, in these young subjects, the bone, although much altered in form at first, becomes remoulded, and in the course of a few years, almost perfect restoration of movement may be expected. Not unfrequently, however, the growth of the bone is, to a certain extent, arrested, and if the separation of the epiphysis had been only partial, it may chance that permanent and very peculiar alterations in form may result. As I have said, we must be prepared for all kinds of displacement, and often it will puzzle the best anatomist to give anything like a confident interpretation of the case; over and over again I have known most remarkable differences of opinion between those who were well entitled to give them, and more than once it has been my lot to save a child from an attempt at the forcible reduction of what was supposed to be an old dislocation, by persuading his surgeon that the case was really one of separation of the epiphysis.

I will not trouble you with citations of cases, excepting just two. One of these illustrates what I have just said as to the formation of lumps of bone, and as to the great difficulty there often is in telling from where they have been detached.

Case 1.—Master L., aged 11, was brought to me by Mr. George Mackenzie, in January, 1882. The history of the injury was that he had fallen whilst running in a meadow, and "dislocated his elbow." His arm in the fall was doubled under him, and his brother rolled on him. The family surgeon, a gentleman of large experience, saw him within half-an-hour, and reduced the dislocation, but said that there was something peculiar in the case, and that he had "difficulty in keeping the bones in." At the end of 5 weeks the boy was taken to a specialist, who used great force, and asserted that he had reduced the dislocation. The elbow was now bent at a right angle, and the hand fastened to the boy's neck. Subsequently, the bandage having been removed, there was, according to the mother's account, a tendency to stiffen in an almost straight position, and the same specialist again forcibly bent the elbow, and fastened it up at an acute angle. The bandage was sealed, in order to prevent its removal, and the elbow kept bent and motionless for three months. It was in this condition that the boy was brought to me, five months after the accident. I found both bones of the forearm dislocated outwards, so that the ulna rested against the capitellum of the radius, and the end of the latter was visible beneath the skin just external to the outer condyle, from which however it was not wholly free. The contour of the inner condyle and adjacent part of humerus seemed natural, and I could not convince myself that there had been separation of any part of the epiphysis.

A most peculiar feature in the case was, however, that in front of the humerus and to the inner side of the ulna there was a large, ill-defined, bony mass. This appeared to be nearly an inch in length, and was deeply placed in the middle of the soft parts. The elbow was so stiff that it was difficult to say whether it belonged to the ulna or the humerus. The most plausible conjecture seemed to be that it had been developed from the coronoid process, which had been completely detached. There was no evidence of other fracture of the ulna, and the outline of this bone from the tip of the alecranon could be easily traced. I advised that the boy should be encouraged to use the elbow as much as possible, and that after a time forcible flexion under ether should be tried. He had at the time I saw him scarcely any movement, either in flexion or rotation.

On Feb. 24, three weeks later on, I examined the elbow under ether, but without establishing any new facts excepting that the mass of bone in front of the internal condyle was certainly fixed to the humerus, and not to the ulna. It was a large hard mass, apparently three-quarters of an inch long. As it was fixed to the humerus, it had probably resulted from some detachment of a part of its epiphysis with considerable tearing up of periosteum. The arm could be bent to less than a right angle, and extended to an obtuse one, but its movements were limited. It was kept in a position of pronation, and could be supinated only to a slight degree.

My next case I quote in order to illustrate a very unexpected direction of displacement of the inner epicondyle.

Case 2.—A young gentleman of 16, whilst playing racquets, fell and struck his elbow against a wall. He was found to have "a dislocation" and within an hour a surgeon reduced it. Nothing further was recognised at the time, but some months later, his father, who was a surgeon, but did not see him in the first instance, found that the inner condyle had been fractured. He was brought to me 6 weeks later, and it was then quite evident that the inner epicondyle was broken

off and displaced downwards, so as to rest against the inner side of the olecranon, where it was fixed a year later. I procured another opportunity for examining the elbow, and found the condition of things exactly as before. On the side of the olecranon was a lump of bone, nearly as large as the end of one's thumb. If not anchylosed to the olecranon, it was certainly very firmly fixed. I could not satisfy myself that there was any motion. The origin of the flexor carpi radialis and also, I thought, a part of the pronator radi iteres could be distinctly traced to this bone. That it was the inner condyle there could not be the slightest doubt, for the part of the humerus from which it had been broken still presented a rough edge, and the condyle had disappeared.

In what manner the displacement of this fragment downwards is effected it is difficult to conjecture, but I have since seen another case, which was in this feature exactly like the one which I have described. Possibly such a displacement can occur only when there is dislocation at the joint, as well as detachment of the epicondyle. Dislocation might be productive of considerable laceration of the soft structures, and be attended by dragging of the epicondyle downwards.

The usual position of the fragment in this accident is, I think, forward in front of the joint, and this is where a knowledge of the muscular attachments would lead us to expect it.

Sir James Paget and Mr. John Wood, both of them, saw and examined the case which I have described. The young gentleman who was the subject of the accident had, when I saw him last, two years after it, regained almost perfect use of the joint.

In conclusion, gentlemen, let me give you a few practical rules for your guidance in dealing with injuries to the elbow joint in young persons.

Never forget the epiphyses, and that they are the weakest part of the bones.

Always suspect that the injury is complicated, in part a dislocation at the joint and in part a displacement at the epiphysal junction.

Remember that simple and complete detachments of the lower epiphysis of the humerus are more common than simple dislocations of both bones backwards.

Never give a diagnosis, if the case is the least puzzling, without putting the child under ether and making a careful examination.

Never be content unless you can easily put the limb up with the elbow well bent.

Be very careful to give a guarded opinion to the parents, knowing that in nine out of ten apparently simple dislocations there is damage either to the coronoid process or the lower end of humerus, and that some impediment to free motion is almost sure to result for a time.

Royal Medical Benevolent College.—The late Dr. William Carr, of Lee, Kent, conceived the idea of founding four free medical scholarships in the College at Epsom, intended for the benefit of orphans of medical men. He contributed largely himself, and obtained subscriptions to a considerable amount, but his death, in March, 1877, prevented his seeing his project carried out, a portion of the necessary sum being then deficient. Mrs. Carr, his widow, who set herself resolutely to accomplish her husband's purpose, has at length collected a sum sufficient to do even more than Dr. Carr contemplated. The original intention was to give each of the scholars £50 per annum, but Mrs. Carr finds herself enabled to increase the allowance to £60; and in addition to this she will have it in her power to present to each of the scholars, on the completion of his studies, £60, with which to commence the world. In this work Mrs. Carr has been liberally assisted by the Duke of Connaught, who, when he was a cadet at Woolwich, was placed under the medical care of Dr. Carr.

ON THE INFLUENCE OF THE AURICLES IN THE PRODUCTION OF CARDIAC SOUNDS AND MURMURS.

Abstract of a Clinical Lecture,

By GEORGE JOHNSON, M.D., F.R.S.,
Professor of Clinical Medicine, and Senior Physician to King's College Hospital.

In the strictly normal state of the heart and circulation, the contraction of the auricles is unattended by audible sound; but there are three pathological conditions in which the auricular contractions are directly or indirectly productive of a sound or murmur. 1st. When the surface of one or both auricles is roughened by lymph, we hear a præsystolic or auriculo-systolic brush or friction sound. 2nd. Dilatation with or without hypertrophy of one or both auricles is associated with audible auricular contraction, and consequent doubling of the cardiac first sound. 3rd. In cases of mitral constriction, a præsystolic murmur and thrill result from the forcible propulsion of the blood current through the constricted orifice by the contraction of the left auricle.

In cases of pericarditis, however circumscribed, it is but seldom that the inflammatory exudation is confined to the auricles: some such cases are mentioned in a clinical lecture which I published in the *Lancet*, May 13, 1876. In these cases a præsystolic brush was found associated after death with lymph on one or other auricle. In one case a præsystolic brush between the left nipple and the sternum, and a systolic brush at the heart's apex, were associated with lymph on the right auricle, and another patch on the apex of the right and left ventricle. In cases of acute rheumatism we frequently hear a præsystolic and systolic brush, or, as we may call it, an auriculo-ventricular systolic brush over the base of the heart, unassociated with other physical signs, or with any local or general symptoms of pericarditis. In a fully developed case of pericarditis, the friction sound, which is commonly described as to-and-fro, is invariably a triple sound, rub-rub—rub. The first two divisions of the triple sound occur in quick succession, and are coincident, the first with the auricular and the second with the ventricular systole, the third friction sound occurs after a rather longer interval, and is synchronous with the ventricular diastole; then follows a pause, after which again occurs the rub-rub—rub. The relation of the triple friction sound with the heart's movements and rhythm may be represented as follows:

Rub	Auricular systole.
Rub	Ventricular systole.
Rub	Ventricular diastole.
Post-diastolic pause.	
Rub	Auricular systole.
Rub	Ventricular systole.
Rub	Ventricular diastole.

If any friction sound results from the auricular diastole, this would be blended with the synchronous ventricular systolic friction sound. A friction sound at the commencement of pericarditis is usually single and systolic, but it may soon become double and triple. When the disease is subsiding, the first sound to cease is usually the auricular systolic, then the ventricular diastolic. A single ventricular systolic brush may be audible for days, and even for weeks, after the other signs and symptoms have passed away. It is important to distinguish these exocardial friction sounds from valvular murmurs. A systolic brush near the apex may be mistaken for the murmur of mitral regurgitation. The diagnosis may be aided by observ-

ing that the friction sound is often much increased, and sometimes rendered to-and-fro, by making firm pressure with the stethoscope over the spot where it is best heard. The exocardial sound, too, is often heard most distinctly, not at the apex, where the mitral murmur is loudest, but above the apex over the body of the ventricle; and it is rarely if ever heard at the back of the chest, where a regurgitant mitral murmur is often distinctly audible.

A study of the friction sound which results from contraction of a roughened auricle has helped me, as I think, to understand and interpret the phenomenon of what is called reduplication or doubling of the first sound of the heart. This doubling of the first sound is of common occurrence in cases of advanced Bright's disease, and I have often observed and demonstrated it in connection with emphysema of the lungs and chronic bronchitis. The late Dr. Sibson and other observers have endeavoured to explain the reduplication in cases of Bright's disease by a want of synchronism in the contraction of the two ventricles. In these cases there is high arterial tension in consequence of an impeded passage of blood through the terminal systemic vessels, and Dr. Sibson supposed that this resistance, reacting upon the left ventricle, compels it to contract more slowly than the right, and hence results the doubling of the first sound. One obvious objection to this theory is, that an asynchronous contraction of the two ventricles sufficient to cause a double first sound must of necessity be associated with doubling of the second sound in consequence of the retarded closure of the aortic valves. Another objection is, that the double first sound is heard most distinctly, not at the apex, where, in accordance with Dr. Sibson's theory, it should be, but over the surface of the heart between the left mamma and the sternum. Then it is questionable whether asynchronous contraction of the ventricles is possible. The interlacing of the muscular fibres of the ventricles appears to render their synchronous contraction a physical necessity; and in watching the exposed heart of an animal in the different stages of apnœa, first in the stage of systemic obstruction with extreme distension of the left cavities, and later during the period of pulmonary obstruction, with great distension of the right cavities and almost complete emptiness of the left, I have noticed the uninterrupted exact synchronism of the contractions on the two sides. I have long been of opinion, and the more I have studied the subject the more convinced I have become, that the true explanation of reduplication of the first sound is to be found in the fact, that *the contraction of a dilated, and especially of an hypertrophied auricle, is productive of an audible sound, and that the first division of the double first sound is the result of the auricular systole.* This theory, which was framed simultaneously and quite independently by M. Potain[1] and myself, is consistent with all the ascertained facts. The rhythm of the sounds in cases of reduplication is precisely the same as that of the friction sounds of pericarditis, in the production of which we have seen that the auricle plays an important part. The triple friction sounds being represented by Rub–rub—rub, the triple sounds in a case of reduplication may be expressed by Rat–tat—tat; not that these syllables express the character of the sounds, but their rhythm. The cantering character of the sounds may be imitated by bringing down sharply upon a board in quick succession the ends of three flexed fingers, making the two first taps nearer together that the second and third. The third is, of course, the normal second sound.

The relation of the triple sound to the heart's movements may be represented as follows:

Rat	Auricular systole	Double 1st sound.
Tat	Ventricular systole	
Tat	Ventricular diastole.	Normal 2nd sound.
	Post-diastolic pause.	
Rat	Auricular systole	Double 1st sound.
Tat	Ventricular systole	
Tat	Ventricular diastole	Normal 2nd sound.

In cases of chronic Bright's disease, the left cavities, both auricle and ventricle, are hypertrophied, and the contraction of the hypertrophied auricle is audible in the 3rd left inter-space (that is, about the line of junction between the auricle and ventricle), immediately before the ventricular systole and sound.

With advanced general emphysema of the lungs and chronic bronchitis there is almost constantly associated doubling of the first sound, which is best heard about mid-sternum. In these cases the dilatation and hypertrophy of the right auricle result from the long continued obstruction to the passage of blood through the lungs. In some cases of co-existing emphysema of the lungs and chronic Bright's disease, both sides of the heart become simultaneously hypertrophied, and the reduplication of the first sound is heard over an extensive surface. I have seen many examples of this complication. It is obvious that the theory of asynchronous ventricular contraction gives no explanation of the reduplication which results from a simultaneous equal, or nearly equal, impediment in the pulmonary vessels, the result of emphysema with chronic bronchitis, and in the systemic vessels, a consequence of chronic Bright's disease; while the auricular theory affords a complete explanation of the facts.

A woman now in Twining Ward, under the care of my friend and colleague Dr. Beale, presents some phenomena which afford much support to the auricular theory of the double first sound. A.P.—aged 29, was admitted for disease of the spinal cord. She is thin and anæmic, the front of the chest is flattened. In the third left interspace there is a visible and palpable pulsation which is immediately followed by the ventricular pulsation at the apex in the fifth interspace, directly below the nipple. It is obvious that the pulsation in the third interspace is auricular; over that space there is a double first sound, the first division of the double sound being unusually loud and distinct, while at the apex the first sound is single, the auricular contraction being there inaudible. There is no apparent cause for the dilatation of the auricle in this patient. There is no evidence of valvular or renal disease. I have observed distinct doubling of the first sound over the base of the heart in other cases of simple dilatation of one or more of the heart's cavities without valvular disease or evidence of arterial obstruction either pulmonary or systemic. These cases are inconsistent with the theory of asynchronous ventricular contraction as the cause of the reduplication.

The theory of the præsystolic or auricular systolic murmur and palpable thrill in cases of mitral constriction which attributes the phenomena to the forcible propulsion of the blood by the auricular systole through the constricted orifice, is now so generally accepted and so obviously true as to require no argument in its support.

One of the main objects that I have had in view has been to point out that a careful comparison of the phenomena of the auricular friction sound, reduplication of the cardiac first sound, and the præsystolic mitral murmur and thrill tends to confirm the theory that the doubling of the first sound is the result of an audible auricular contraction and not of asynchronism of the right and left ventricular systole.

[1] "D'un Phénomène Stethoscopique propre à certaines formes d'hypertrophie simple du cœur," by Dr. EXCHAQUET, Interne des Hôpitaux de Paris, 1875.

CLINICAL LECTURES

By J. MATTHEWS DUNCAN, M.D., F.R.S.,
Physician-accoucheur and Lecturer on Midwifery at St. Bartholomew's Hospital.

Lecture III.

TERMINATIONS OF PERI- AND PARA-METRITIS.

You cannot fail to notice the great abundance of cases of this kind in "Martha," half of the beds often being occupied by them, and this commonness is one great sufficient source of importance. Hence also the amount of attention they deserve from you.

You, further, cannot fail to have observed that, while some are tedious, most or nearly all go away with local and general health restored. The sufferers lie in bed under treatment, ailing and sickly, with a temperature chart of rises to 101° or even higher, and falls to normal or a degree below it: then, and often almost suddenly, and generally after three or four weeks, the rises and falls are reduced within the limits of one degree or thereabout, cheerfulness appears, and beauty returns. But there are occasionally fatal cases—septicæmia, pyæmia, sloughing, hæmorrhage, exhaustion, being assigned as causes: they are rare.

It is not the ordinary course of perimetritis and parametritis that I am to consider in this lecture. I desire to call your attention to the rare cases which do not end more or less directly in death or recovery; but in which there are injurious or fatal consequences of the original disease.

The perimetric matting together of parts gives rise to misleading feelings, as of lumps or tumours, and is sometimes very slow in disappearing, the process even occupying years. When such chronic cases come before a practitioner who is unacquainted with the history, he is very liable to be misled into diagnosing fibroids or even cancer: and the aching which the patient has in the lumps, or in the back and limbs, may increase the tendency to mistake.

In the early days of gynæcology (about the first quarter of this century and later) it was held that pregnancy occurring during the persistence of such adhesions entailed great danger to life from abortion and its consequences. But we now know, from large experience, that abortion is very far from being an invariable result of adhesions of the gravid womb, and that danger to life is little increased by them. The minute details of the behaviour of the adhesions, in pregnancy, are not yet described, but of some important points we may be sure. The growing uterus may stretch the adhesions, making more or less long bands, such as are seen in cases of past pleurisy; or, by combined stretching and the rubbing of incessant come-and-go motion, they may be made to disappear altogether. Sometimes, when adhesions are firm, old, and organized, they are not destroyed in this way, but persist till the end. In such a case they may give much trouble during labour. A case was, some years ago, under my care, in which they led to what has been described as persistent retroversion of the gravid uterus. In that case the uterus never became free or mobile.

There are on record some very rare cases where an ovary or a tube, or both, are found isolated, separated from the rest of the genital organs, and adherent to some remote part, say to the colon. This is believed to be produced by well organized strong adhesions, so strong indeed as, in the trial, to prove more tenacious than the natural connexions of the part. The rarity of the occurrence arises from the rarity of such strength of adhesions, and we have already said that, as a rule, they quickly give way when subjected to tension. Peritonitis occurring after delivery may lead to such adhesions high in the abdomen; and then, it may be long after the adhesions were produced, the uterus is pushed down by force sufficient to put the adhesions on the stretch; and, the adhesions not giving way, the force leads to giving way or division of the adherent tube or of the structures connecting the ovary with the broad ligament. The uterus descends, leaving behind it the ovary and tube attached to the colon.

The indurations of parametric inflammation are sometimes very slow in disappearing, and slowness is fostered by work, exposure to hardship, or indiscretions in conduct. Generally, and especially if the patient lies in bed, these indurations melt away more rapidly than those of perimetritis. As they are in progress of contraction and dissolution, they pull the uterus to their own side, and keep it fixed.

Pregnancy may occur at any stage of a parametritis, and be disturbed by it; or, if the pregnancy goes on smoothly, the parametric induration may disappear as it advances. Sometimes, in early pregnancy, the practitioner is, in such a case, alarmed by the fixation of the cervix and its great displacement; and, while I have had to partake in this alarm, I have not seen as yet any disturbance of the progress of labour by it, even though examination after convalescence from confinement showed that the morbid condition still in some degree persisted.

One of the most interesting and practically important points in parametric induration is the rate of its disappearance and the causes of arrest of this good progress to annihilation. It is quite sure that the rate of disappearance varies much, and that it is accelerated by nothing so certainly as by persistent comfortable lying a-bed. A parametric induration or phlegmon is a tender, convex swelling, at first, and pushes the uterus to the opposite side of the pelvis. As recovery begins, it shrinks and becomes flat; and, as convalescence is established, it shrinks more and more, becomes densely hard, concave, and draws the uterus to its own side. At last nothing is felt but the fixed uterus, nailed to the affected side of the pelvis by a very limited dense concave hardness which is not tender to touch. When this stage is reached, we have all the indications of convalescence, and the patient is soon discharged from the hospital, after a residence of from four to eight weeks. The return to home and its duties does not prevent the further desirable progress of the case, the hardness being gradually relaxed and softened, and the uterus regaining mobility and returning to its natural place in the pelvic excavation. Where this relaxation and softening of the parametric induration does not take place or takes place imperfectly, you have a case of what is called parametritis atrophicans.

I have said that return to home and its duties does not prevent completion of recovery, but I believe it always retards it: and we had lately a case in "Martha" where this retardation was so great as to be very noteworthy and instructive as to times. It was indeed scarcely a retardation, rather an arrestment of progress for twelve months. J. C., æt. 22, left the hospital in January, 1882, convalescent, after a left parametritis, not puerperal. The uterus was then fixed and drawn to the left sacro-iliac synchondrosis. She returned in February, 1883, because of increased aching of left hip, menorrhagia, and irritability of bladder. The uterus was found to be as it was when she left the hospital. After four weeks' residence in "Martha" she was dismissed cured.

This patient, you observe, returned to "Martha" after a year's absence in nearly the same condition as when she left it. Finding the uterus fixed to the left side of the pelvis by concave and very narrow induration, we concluded that we had a case of parametritis atrophicans, and we were in error. It was a case of

arrest of progress for the long period of twelve months. The arrest came to an end when proper means were resorted to; and progress was rapid, the uterus gaining the middle of the pelvis as it became freely mobile. The chief of the proper means of recovery was lying in bed, and this she did for a month: besides this, we used local antiphlogistic measures—leeches and mercurial ointment—because there was aching lately increased and some tenderness on pressure. On the use of mercurials I may here interpolate one remark. That they are useful in some inflammatory conditions no one doubts, but they have been said to be useful in destroying old peritoneal adhesions, and this I do not believe. Adhesions are, so far as my experience instructs me, destroyed only by the mechanical processes of rubbing or stretching, or both. But parametric induration may be at any time beneficially affected by mercurials, if it has not reached the inveterate state of atrophicans.

We have said that the uterus may be permanently—that is, for life—fixed by adhesions; and so it may be by the results of parametric phlegmon or abscess. When it is fixed by the cicatricial tissue of a healed abscess the result is easily comprehended: but sometimes, without abscess, the phlegmon, or inflamed cellular tissue, becomes like the tissue of a cicatrix; it has atrophied and become more or less tight or hard—the parametritis has ended by being atrophicans: and by the atrophied tissue the uterus is more or less fixed. Chronic fixation by adhesions is rarely a cause of aching or any kind of suffering, but fixation by this cicatrix-like tissue is not very rarely so. The suffering is that of neuralgia—an aching felt near the part; and it may be intermittent.

Some of the neuralgic aching ascribed to chronic parametric induration may be due to ureteral irritation or obstruction. Ureteritis and ureteral obstruction do both occur occasionally, and it is natural to expect that they will cause some kind of suffering. You must not forget that, besides causing pain, ureteral irritation and obstruction may lead to disease of the kidney—Bright's disease—hydronephrosis—pyonephrosis.

Perimetritis is more rarely a cause of disturbed function of the rectum and bladder, or of inflammation of them, than parametritis. In both rectum and bladder the disturbance arises mainly from more or less severe inflammation communicated to them by contiguity: and of course the suffering is much greater in the vesical than in the rectal complication, and the suffering is greatest when you have a parametritis anterior. In the case of the bladder, the disturbance is very rarely, if ever, mechanical; while in the rectum, if the fæces are not fluid, mechanical disturbance or a degree of obstruction is not very rare.

In perimetritis you may have obstruction of the sigmoid flexure, of the rectum, or of the ileum, by bands of adhesion. Of such accidents I do not here speak: they have no gynæcological peculiarity. In Dr. Church's ward we saw a fatal case of this kind, the ileum being strictured. Parametric partial obstruction of the rectum is rarely sought for, for it is rarely so great as to attract attention. We have lately had several cases of it in "Martha." The obstruction is about as high as the finger can reach, the bowel being encircled by a ring of tissue as hard as bone, the whole firmly fixed and immovable. This condition, in a chronic case, coming before you for the first time, and perhaps without a history, is liable to be mistaken for cancer. In one of our parametric cases, with a sufficient history, it was lapse of time and absence of progress, which alone enabled us to reach assurance that we had not malignant induration. In this case the stricture was so tight as to transmit no more than a finger, and the fixation extended even to the mucous membrane of the stricture part: and the mucous membrane was swollen and not smooth on the surface. These conditions of the mucous membrane lasted only a few weeks, but the stricture persisted when we last saw the patient, about six months after her first dismissal: it caused little trouble. In most cases the morbid rectal conditions disappear just as the main parametric induration goes away.

There is, as I have said, rarely much disturbance by the rectum: oftener by the bladder, and the cystitis may lead to renal disease. The danger from the bladder is easily stated: it is the risk of the cystitis being severe and becoming chronic; the bladder becoming contracted—the case perhaps incurable. The symptoms of cystitis, acute and chronic, and the difficult, and, I am sorry to say, very unsatisfactory, treatment of these affections, do not fall to be considered here.

When long persistent matting, consequent on peri- or on para-metritis, or on both, is found, you should suspect the presence of one or more sinuses, or of sacs of matter, and carefully look for them. There may be no need of searching to find them, for they often open in the groins. Rarely they are found opening in the vaginal roof. They often open in the rectum and bladder, but then openings in these viscera are very rarely discovered. You find induration around the womb, and you find a constant or intermittent discharge of pus per rectum, or per vaginam, or per urethram, and you conclude that there is a sinus, although you cannot find it. We have a preparation from a chronic case which proved fatal by peritonitis acutissima in another region; it shows sinuses opening into the bladder, the rectum, and the uterus.

Lately we had in "Martha" an interesting case worthy of mention here. The woman was 44 years of age, and had been ill for a whole year—that is, since her last confinement with her fifteenth child. She thought herself again pregnant. There was between the uterus and bladder, and rising to within an inch of the navel, a displaceable rounded hard tumour. Three weeks before admission there was a great flow of pus with the urine, and since that time it has always contained a large quantity of pus, but there is no notable increase of mucus. There has been no irritability of bladder: the probe introduced into the bladder made it out to be only slightly contracted and slightly tender: and these circumstances, corroborated by the absence of mucus in the urine, led us to believe that there was only very slight inflammation or only irritability of the bladder, and that the pus must come, not from the bladder, but from elsewhere through a sinus opening into the bladder. At this time we regarded the tumour as probably solid. There being no prospect of our ameliorating the condition of the poor patient, we resolved to search farther for the source of the pus, and with this view dilated the urethra. Then, passing the finger into the bladder, I found a slight prominence on the tumour, rounded, and having on its summit a roughness, and into this, and so into the tumour, it was easy to introduce a probe, and diagnose a suppurating cavity. The pus was discharging freely and the tumour steadily diminishing; the temperature, which had ranged from 101° to 98°, ranged from 98° to under 100° when she left the hospital, to return again for further examination and perhaps further treatment.

Sinuses when established may run very long—years—and then fortunately heal up, and gradually complete cure follows. But you must not forget that sometimes the abscesses unopened persist for years, probably diagnosed as fibroids. We had in "Martha" lately a case that we estimated of five years' duration: it contained fetid pus and fetid gas, and only required opening near the anterior iliac spine. Old sinuses in the neighbourhood of the womb have probably the same pathology as those elsewhere, and they demand

the same treatment. Their persistence depends on mechanical conditions impeding evacuation of a cavity or cavities and healing, or on depraved general health, or on some diseased organ, as a tuberculosis of the ovary, keeping up suppuration. After careful surgical examination and consultation you will do your best by medicine or by the knife. Rarely the cause of delay in healing is carious or necrosed bone, and for the treatment of such a case you have ordinary surgical guidance. Lately, in "Martha," we had a case in a young woman where caries of the crest of the ilium retarded the healing of a large parametric puerperal abscess.

I have read of cases where dysentery was the cause of fatal termination, but I have not seen any. In a fatal case just to be mentioned there was severe diarrhœa. Several cases have come under my notice where persistent sinuses with prolonged suppuration have ruined the constitution and destroyed life by inducing pulmonary or renal disease.

We have just had in "Martha" a good example of death from a chronic perimetric abscess coming on after delivery, and remaining unopened. It led to degeneration of vital organs, and specially of the kidneys, the end being somewhat suddenly produced by an attack of general peritonitis. E. W. bore her second child 20 months before admission to the hospital. She then caught cold, and has never been well since, suffering much from pain in the hypogastrium. For a year she has been getting thinner and weaker, and about four months ago she had much painful diarrhœa. For the last three months she has been confined to bed. Now she is extremely weak and emaciated. Heart has a systolic murmur at apex. Urine copious, of low specific gravity, having a varying but large quantity of albumen. Belly tympanitic. Labia and lower limbs œdematous. Just above the brim of the pelvis is felt a hard, tender, mass, dull on percussion. Vaginal examination finds this hardness, the uterus being displaced backwards, and the bladder found to be extended below the hardness which was diagnosed as a chronic abscess. In this case the bladder prevented us from aspirating per vaginam, and we held a consultation with Mr. Willett, as to opening by dissection through the hypogastric wall. This we decided not to do, because the patient was almost moribund, and we believed the interference would only accelerate the progress to death. At this time the urine was half albumen. The temperature was 97° or 98°, making a sudden rise to 106·6° the day before her death, when it was 97·6°. The pulse varied from 80 to 100. The post-mortem revealed general peritonitis; dilated kidneys, of which the right was pale and fatty, the left pale and disorganized; a sago spleen. A large perimetric abscess was found above the bladder and in front of the uterus, which was pushed backwards, and having its fundus projecting into the abscess-cavity. Both ovaries were cystic, about the size of a hen's egg, the cysts being filled with purulent fluid.

Lastly, I mention some affections of the lower limbs, which, though not ending fatally, are very grave and troublesome. The common parametritic retraction of a limb generally disappears quickly with the disappearance of the disease causing it. Sometimes, in sensitive women, it is a matter of great difficulty to get the thigh again extended and useful. This may arise from mere sensitiveness, or from injury that has been inflicted on the psoas and iliacus muscles. In such cases you may even have to use orthopædic machinery to get the limb extended and restored to use.

Lately a fatal case of parametritis post partum was examined in the post-mortem theatre, and the psoas muscle was found to be destroyed, its place taken by the abscess, and through it, stretched like fiddle strings, passed the bare nerves. This case was fatal; but, no doubt, instances of recovery, after more or less of such destruction, occur; and I mention this case to prepare you for the occasional but rare occurrence of permanent injury to the lower limbs, the injury being of various kinds. I know a case of complete paralysis of a limb, with atrophy, and without contraction. Cases also occur of paralysis of certain sets of muscles; and of paralysis with contraction. Sometimes there is atrophy of the limb, and occasionally a kind of elephantiasis, such as one sees after phlegmasia dolens, and probably owning the same obstructive venous pathology.

If the hip joint has been injured, as by pus forcing its way into it, an event which is on record, you will, if the case survives, have to ask the advice and aid of the surgeon.

ON A RARE FORM OF ITCHING VESICULAR ERUPTION (? HYDROA BULLEUX OF BAZIN).

By ALFRED SANGSTER, M.B. Cantab., M.R.C.P. Lond.,
Physician for Diseases of the Skin, Charing Cross Hospital; and
J. MITCHELL BRUCE, M.D. Lond., F.R.C.P. Lond.,
Physician to Charing Cross Hospital, and Assistant Physician to the Hospital for Consumption, Brompton.

The following cases of this disease, which have recently been under our observation, appear to us to deserve careful record. The condition is of special interest, not only because of its rarity (only a few instances having been described), but because, whilst it occupies a position on the borderland of several kinds of skin disease which possess well understood diathetic relations, it cannot as yet be definitely referred to any one of them.

Case 1.—F. B., a portmanteau maker, æt. 20, a tall, thin, but fairly healthy-looking man, presented himself as an out-patient at Charing Cross Hospital in March, 1882, complaining of disease of the skin.

His parents were living and healthy. Of 7 brothers and sisters, one brother was "rheumatic," and another had had rheumatic fever; a sister was said to suffer with a skin affection similar to that about to be described. A grandmother was also said to have had an eruption round the waist of a like character.[1]

He himself enjoyed good health, with the exception of his skin disease and the lassitude induced by disturbed rest. The heart and lungs proved to be sound; the urine free from albumen and sugar. There were scars in the groin from venereal disease, contracted about one year before, but apparently not syphilitic in nature. Since leaving home, some twelve months previously, he had lived indifferently, fish (mostly dried) and shellfish forming a large part of his diet, so that he took on an average ten to twelve fish meals in the course of a week.

On examination of the skin, the following condition presented itself:—Over the trunk, back and front, was a profuse eruption, made up of circular pale red patches, with slightly raised margins, presenting isolated, but somewhat closely placed, vesicles or small bullæ, intermixed with brownish crusts and excoriations. In front the patches were almost confluent, and exhibited a very perfect symmetry of distribution, so that the chest presented an almost continuous erythematous area, bounded by a festooned border corresponding to the margins of the ribs, the border studded with the vesicles and crusts above described.

[1] On personal enquiry, these affections turned out to be Herpes zoster.

Elsewhere on the trunk, the eruption was more broken up, the circular patches less perfect, and more widely placed. Here and there segments only of circles could be traced, or curvilinear outlines, but all were more or less raised and vesicating. The arms and thighs were similarly affected, but in a minor degree; whilst on the thighs and buttocks there were, in addition, many isolated ecthymatous crusts situated on inflamed bases. The legs, forearms, backs of hands, and dorsa of feet were most free from eruption, showing only a few isolated serous and blood crusts placed abruptly on the surface—*i. e.*, unattended by any inflammatory evidence. There were a few scattered crusts of a like character on the neck and face. The vesications were all small, not exceeding a split pea in size; for the most part they were shallow and irregular in outline, and filled with a clear or slightly turbid straw-coloured fluid. A few patches exhibited vesications in the same stage of evolution, but, as before said, they were mostly intermixed with crusts and excoriations. The patient complained that the eruption itched intensely; he habitually scratched the patches when the body was exposed. The many excoriations betrayed the injury done to the vesications by the finger nails, and confirmed the pruriginous nature of the eruption. According to the patient's statement, this condition of skin had been present in varying intensity for about eight months. No medicine had been taken before he came to the hospital. He had never suffered from any skin ailment before.

The above-described eruption steadily disappeared under expectant treatment (alkaline gentian mixture), so that within a month only slight pigmentations remained at the seat of the vesicating patches. Ecthymatous lesions over the thighs and buttocks were still present. The patient continued under observation for 15 months, during which time many partial relapses occurred, and some few acute general outbreaks, such as that described (according to the patient, five). He does not think the body has remained free for longer than three weeks together. In some of the partial relapses the type of eruption was so changed as to present but a very slight similarity to the strongly characterized eruption first seen. For instance, in some relapses there appeared distinct wheal-like lesions, surmounted by vesicles, small bullæ, or excoriations, these being intermixed with single pea-sized bullæ, or small aggregations of vesicles, without accompanying œdema or erythema. All such lesions were liable to present excoriations, the result of scratching. In one attack he had sores in the mouth (palate). In the partial relapses the ringed or patchy character of the eruption was generally suppressed, or but feebly represented. Quite recently the patient again presented himself with a general outbreak, when a portrait of the disease was taken as it affected the trunk and upper extremities. The appearances depicted may be briefly described as follows:—From the root of the neck to the umbilicus the surface is thickly covered with erythematous patches, presenting the greatest irregularity, but mostly of a gyrate or ringed pattern. Nearly all are covered with closely-set straw-coloured vesicles or bullæ, scarcely larger than vesicles. Here and there are rings and S-shaped patches of vesicles, unaccompanied by inflammation.

About a month after the patient first came under notice he began to take arsenic, and, according to his statement, with marked benefit. On this point he has always been most positive, maintaining that a few doses were sufficient to cause the rapid disappearance of the eruption, or check a severe outbreak, which he says he could always predict by the general and extreme itching of the skin. This statement has never been verified, but the strongest reason for believing it is the fact of his continued attendance at the hospital at considerable inconvenience—merely to get the medicine.

Another statement there was reason to credit was, that during an attack some of the wheal-like lesions were produced by scratching or rubbing.

With this case may be mentioned another, which came under observation as long ago as 1877.

Case 2.—R. P., æt. 32, presented himself at Charing Cross Hospital, with an affection of the skin, having the following characters:—The eruption was almost general over the trunk and limbs, and consisted of circinate patches becoming confluent; the margins of the patches presented small vesicles and crusts, so that many patches appeared bounded by a ring of vesicles. There were also discrete vesicles, or small bullæ, scattered over the surface, and even between the fingers. There was much evidence of scratching. Some raised red patches were seen not vesicating. The face and neck were the regions least affected. The itching was complained of as almost unbearable. Exposure to the contagion of syphilis was admitted.

Careful search for acari was made, but with a negative result. No diagnosis was arrived at. Unfortunately the case was soon lost sight of at Charing Cross, but it created considerable interest elsewhere. The patient was admitted into the Middlesex Hospital, under Dr. Cayley, who permitted Dr. Tilbury Fox to take notes of it.. In a communication to the *Archives of Dermatology*, 1880, entitled "A Clinical Study on Hydroa," by Dr. Tilbury Fox, edited by Dr. T. Colcott Fox, the case is alluded to as follows:—"He [the patient, R. P.] is at the present time covered with a large vesicular or small bullous eruption, even to the palms of the hands and soles of the feet. Some parts are less affected than others; thus the back of the trunk less than the front, the head and face very slightly, only a few existing over the whisker area and scalp, the legs very thickly. These small bullæ vary in size from a pin's head to a small pea, but the smaller appear to grow to the larger size, and then usually get umbilicated; the contents get partly absorbed, partly dried up, and a leafy scale is left, which, when joined side by side with others, form large tracts of foliaceous crusts, reminding one of a miniature pemphysis foliaceus. Under these scales a hyperæmic, pigmented, but not excoriated surface is left. When very small, these vesicles have clear contents, but the latter rapidly become milky and yellowish. The eruption rises directly as a vesicle, and there is no precedent erythematous papule to be seen. They are discrete and also aggregated in places in little groups of three or four, but on the left shoulder there is a distinct herpetiform cluster two or three inches square. They are not evolved in rings or festoons, as in inpetigo herpetiformis; and there is one continual succession of vesicles coming out, but more abundantly, the patient thinks, in the night. Lastly, the itching is intense, and consequently many vesicles get broken, and a hyperæmic spot is left, crowned by a reddish black crust."

This was the last of several attacks the patient had had since the first appearance of the eruption. Whilst in the Middlesex Hospital, the patient was shewn at the Medical and Chirurgical Society by Dr. Evans (see *Med. Chi. Proc.*, Feb. 13, 1877), who considered it an example of the disease described by Hebra as *Acne Cachecticorum*. In the account of the case the patient is mentioned as having had five relapses in three months.

It is specially interesting to note in this case that when first seen at Charing Cross Hospital, the markedly ringed type of eruption was altogether different from that described above as the condition present when the patient was in the Middlesex Hospital.

In this respect the case resembled the one (F. B.) first related in this paper—other points of resemblance

being the relapsing character of the eruption, and the extreme itching.

Case 3.—Mrs. C., æt. 21, the mother of one child, came to the out-patient department of the Brompton Hospital on November 13th, 1882, suffering from chronic phthisis of both upper lobes, and from an extensive and severe eruption on the skin.

The family history was remarkable:—The mother, sister, and seven brothers of her mother's father, all died of phthisis. Her mother's mother and brother both suffered from the same disease of the skin, and her mother was still the subject of this condition (and attended shorly afterwards as Case 4). In the case of the grandmother, the disease disappeared at the climacteric period. The only child of the patient, æt. 18 months, exhibited within the first year of life, one or two blisters as large as a pea, but no extensive eruption at any time. Her father was said to have died of cancer of the lungs.

For 6 years she had had cough in winter; and she was now suffering from the usual symptoms of phthisis of very moderate intensity. The present eruption began at the age of 8, since which time she had never been free from it for more than two years—between her 13th and 15th years. The disease was worse during pregnancy.

On the occasion of the first visit, the patient, who was a weakly woman with a badly nourished, rather flushed aspect, presented no active manifestation of the eruption. On her return, after three weeks, she stated that 14 days before, on November 20th, a fresh eruption of the usual kind had made its appearance. During the night chiefly, the skin began to itch intensely; wheals rose, as in nettle-rash, and very quickly became small blisters; and these were either ruptured by scratching, or broke spontaneously in the course of a day. For another day the spots continued to weep, and they then healed.—On examination it was found that the whole of the front of the abdomen, the loins, the thighs and the legs, were covered with patches of skin-disease. This consisted of urticarial wheals, bullæ, and vesicles of various size, partly whole and partly broken, and remains of dead epithelium clinging to red, pigmented, or raw areas of the skin. The itching was still intense, so that the patient was unable to refrain from scratching the skin during examination. The most profuse part of the eruption corresponded with the waist, the region of the umbilicus, the shoulders, armpits, buttocks, thighs, and garter-region, and one patch occupied the areola of the right breast. The lower limbs were less profusely covered than the trunk, the abdomen presenting hardly a single spot of skin which was not affected by the disease in some stage or other. The head, neck, and arms were perfectly free.

One month later it was found that the old eruption had entirely healed, and that fresh spots had come out steadily. On February 8th, 1883, the skin was almost free from disease; but by March 1st, fresh crops were appearing, and Liquor Arsenicalis ℥ iii was ordered three times a-day. Three weeks later there was no improvement; the arsenic was followed by sickness and occasional diarrhœa. The dose was therefore reduced to ℥ ij. t.d.; and in the course of the next two months there was a very decided improvement in the state of the skin, the eruption being entirely absent for longer periods, and less severe in all respects when it did re-appear.

Case 4.—Mrs. W., æt. 45, the mother of Mrs. C., case 3, referred to above, came as out-patient to the Brompton Hospital on April 2nd, 1883, suffering from cardiac disorder, and an eruption similar to that on her daughter. The family history has been recounted above.

The patient has had 6 children and 5 miscarriages, and was always weakly after her confinements. The eruption has appeared at intervals, "as long as she can remember," and was always worse before menstruation and during the whole time of her pregnancies, so that she could tell she was *enceinte* by the state of her skin. *Post partum* she always improved. The longest period of freedom from eruption was about 3 years, whilst she was at Brighton. The affection has always involved by preference the same regions of the body as in her daughter, except that the shoulders have escaped. The arms, face, and ears have always been free. Itching has been intense at all times, and the eruption smarts when the blisters have broken.

A rather thin, but not specially anæmic woman, with a flushed, nervous, heated appearance, active and intelligent, she now presents patches of a rough pigmented appearance over the front of the abdomen, evidently the remnants of a past eruption. She says that any irritation of the abdominal wall would suffice to bring out "lumps" with great itching, and occasional vesication, but that the condition is much less marked now than formerly. The lungs are healthy; the pulse varies much in frequency; the cardiac impulse is distinct, rather low and towards the left in situation; the sounds are loud, but there is no murmur. The patient suffers from occasional palpitation and left submammary pain. Digestion is fair; bowels regular. Menses still regular. To have ℥ ii Liq. Arsenicalis t.d.

Three weeks later, the patient said she felt stronger for the medicine. The eruption was certainly less, no large spots being visible, but a small eruption came out when she was heated, with great itching, which "would raise the spots if she yielded to the desire to scratch." The patient spontaneously stated that perspiration had been less since the mixture was begun. To have ℥ iii of the Liquor Arsenicalis t.d.

Again in three weeks, the eruption proved to be less severe in degree, but to be as readily induced by heat. Ordered ℥ iv of the arsenical solution t. d.

One month later, the eruption was found to be insignificant—in the form of a diffused redness of the skin, without vesicle or sore, but still itching.

A considerable number of cases more or less resembling those above related are to be found scattered through recent medical literature, under various names, but chiefly under the name of *Hydroa*. Whether they deserve a distinctive name is still debateable. On the one hand, there is felt the want of a name for these cases, which may be said to possess a certain individuality; on the other hand, there exists a laudable desire to simplify as much as possible the already encumbered nomenclature of skin diseases, and above all not to distinguish by fresh names diseases which do not differ essentially from others which are already named.

As some obscurity attaches to the extent of the modern acceptation and application of the term Hydroa in this country, a short *resumé* of the subject may not be out of place. *Hydroa* (ὕδωρ, water), is an old Hippocratic term. Bazin revived it and applied it to a group of cases which he said occurred in arthritic subjects, hence the heading under which hydroa, with other diseases was classed, namely, "*arthritides*."

Three varieties were described:—1, Hydroa vesiculeux; 2, Hydroa vacciniforme; 3, Hydroa bulleux (*pemphigus à petites bulles*). The first variety, *Hydroa vesiculeux*, may be briefly described as a disease which may or may not be ushered in by slight constitutional disturbance. Numerous slightly-raised red and circumscribed disc-like blotches appear most constantly on the backs of the hands and wrists (other regions may be affected). In size the blotches range from that of a lentil to that of a 20-centime piece. Soon there appears a transparent vesicle (or small bulla) which rapidly desiccates in the centre, while the

fluid at the circumference becomes re-absorbed. The lesions now put on a special appearance—little red discs are seen with central courts surrounded by a whitish slightly-raised ring. This ring is formed by the macerated and detached epidermis left after the partial re-absorption of the fluid. Successive crops of eruption take place, and the disease may be prolonged for a month. The buccal and labial mucous membranes may be similarly affected.

The second variety, *Hydroa vacciniforme*, may be passed over—Bazin saw only one case, and attempts by other observers to identify the disease have not been successful.

The third variety, *Hydroa bulleux*, is the only one we are most concerned with in connection with the cases just detailed. Bazin's description is nearly as follows:—Hydroa bulleux is an arthritic affection but litttle known. An eruption preceded by malaise, loss of appetite, and slight febrile disturbance, is seen on the arms, trunk, insides of thighs, and occasionally the buccal membrane—the only prodromal phenomenon which seems constant is intense pruritus. The eruption consists of bullæ filled at first with clear fluid, but soon becoming opaque yellow. They occur in groups of three and four on a red surface. The bullæ are unequal in size, ranging from that of a lentil to that of a split pea, which size few exceed. While fresh bullæ are coming out, the older ones dry up and are replaced by a yellow crust. The patient retains his appetite, and nutrition is not interfered with. The disease runs a chronic course, manifesting itself by successive outbreaks and lasting altogether five or six months.

The above then are two diseases to which Bazin gave the name of Hydroa. It seems, however, that they had been described in this country by Willan and Bateman—the first under the name *Herpes Iris:* the second probably under that of *Herpes Phlyctænodes.* Herpes iris was described by those authors as a disease possessing similar clinical features to those peculiar to Hydroa vesiculeux. It was characterized locally by disc-like lesions with concentric vesication. Bazin, after he became acquainted with Willan and Bateman's description of Herpes iris, admitted that the disease was identical with Hydroa vesiculeux.

Some time ago Hebra published his views concerning the nature of erythema—the form of it which runs a definite course and has a special tendency to affect the backs of the hands and wrists, insteps, face, &c. He showed that whether the disease appeared in the form of papules (E. papulatum) or in the form of tubercles (E. tuberculatum), in the forms of single rings (E. circinatum), or concentric rings (E. iris), the clinical symptoms were the same, and united them all in one common bond. Further than this, Hebra recognised the fact that the inflammatory process giving rise to this erythema was one which observed no abrupt limit, and that it frequently terminated in the separation and exudation of the watery principles of the blood between the epidermis and true skin; at such times leading to vesication in various forms. It was but a short step, therefore, to include Willan and Bateman's Herpes iris, which, although possessing certain peculiarities, was obviously of the same nature.

For all these different forms of the same disease Hebra invented the term *Erythema exudativum polymorphicum.* As regards the use and application of the term Hydroa in this country, it has been applied to vesicular forms of erythema multiforme indiscriminately (Report on Hydroa, *British Medical Journal*, 1870). Later still (1875) it has also been applied by Mr. Hutchinson to vesicating forms of Iodide of Potassium eruptions.

So far an attempt has been made to elucidate the subject with regard to Hydroa vesiculeux. It remains to be considered what cases are to be identified as corresponding to the other variety, Hydroa bulleux, and what their relation may be to other diseases.

Besides the cases detailed above, which are assumed to correspond to Bazin's Hydroa bulleux, other cases of a like character will be found in the article referred to by Drs. T. and T. C. Fox; and others again in an article by G. H. Fox, of New York, in the *Archives* for July, 1878. It may be pointed out (1) that the distribution (back of hands, forearms, face, insteps) is in these cases not specially noticed; the eruptions are general, with a tendency perhaps to exempt the face. (2) Itching is a very constant and most marked symptom. In these respects they differ from the cases which belong to Erythema multiforme (Hydroa vesiculeux or Herpes iris). Again (3), the eruption relapses over a period of many months. Although this is only a question of degree—the erythemata tending to relapse—yet these Hydroa bulleux cases are certainly more chronic. Lastly, there are (4) the objective characters of the eruption—lentil-sized to pea-sized small bullæ, varying in their arrangement in individual cases, and in different relapses in the same case, occurring singly, in groups, or in circles or segments of circles, the whole complicated with secondary lesions due to scratching—viz., excoriations, urticarial wheals, and ecthymatous lesions from the inoculation of pus. Thus it comes about that the appearances presented by these eruptions are some of the most complex and bizarre it is possible to meet with.

Are these cases, then, sufficiently individual in their characters to constitute a group by themselves? or is it possible to recognise in them examples of more well known diseases, so to speak, in disguise? For reasons already mentioned, they seem not to be so closely related to the erythema group, but to bear a close resemblance to other diseases, such as Pemphigus, Herpes, and Urticaria. Bazin notes the fact that the disease he described as Hydroa bulleux was already known as *Pemphigus à petites bulles.* Such cases have also probably furnished material for the description of Pemphigus pruriginosus. Recognising the danger of judging by anatomical appearance, it must be admitted that the pemphigus bulla is, as a rule, very different from the large vesicles or small bullæ encountered in this disease. Especially may be mentioned its peculiar abrupt character or absence of surrounding inflammation. Both diseases relapse over a period of months or years; but in Pemphigus a cachexia is readily established, which at times proves fatal. None of the cases described as Hydroa bulleux seem to have materially influenced the health. There is one fact (if it be a fact) that would help to link these curious cases with Pemphigus, and it is the influence on them for good of arsenic. The drug is not mentioned as having been tried in many cases; but what facts are noted, are favourable as to the benefit derived from it.

The cases bear a certain resemblance to Herpes in the grouping and fleeting character of the vesicles. No special nerve distribution is affected however; the grouping is not of that corymbose character peculiar to Herpes zoster; nor are the attacks associated with catarrh or rigor, as is the case in catarrhal herpes.

But perhaps these cases fit in with urticaria as well as with any other disease. The intense pruritus, the general distribution of the eruption, its erratic character and tendency to vary in pattern, especially to affect ringed and serpiginous types, its relapsing tendencies and probable localization in some cases by mechanical irritation of waist bands, garters, &c., are all points suggestive of urticaria. With regard to the last mentioned peculiarity, it may be conjectured that these cases, where the disease persistently attacks the mechanically irritated positions, are analogous to those

cases of so-called "factitious urticaria," where the simplest mechanical irritation is sufficient to raise a wheal.

There are, however, no ætiological facts as yet available to support the urticarial relationship, unless the arthritic tendencies which are common to the two diseases be accepted as such. Lastly, the anatomical appearances of the eruption present but a trifling objection, when it is remembered that experience has taught us to attach but little importance to these in association with diseases presenting cutaneous lesions of a purely inflammatory type. Polymorphic exudative erythema is now recognised; would it not be as well to admit a polymorphic exudative urticaria? Cases of "Urticaria bullosa" have been already described.

For such cases then as those detailed above, at any rate until more is known about them, there is some reason to retain the name Hydroa. As for the other variety, there seems to be little room for the name, inasmuch as they are well included as cases of polymorphic erythema.

REPORTS OF
HOSPITAL PRACTICE IN MEDICINE AND SURGERY.

GUY'S HOSPITAL.

JAUNDICE FROM IMPACTION OF GALL-STONE IN COMMON BILE-DUCT. GENERAL TUBERCULOSIS WITH TUBERCULAR PERICARDITIS, AND MENINGITIS. DEATH.

(Under the care of Dr. FREDERICK TAYLOR.)

T. T. H., æt 60, was admitted into Guy's Hospital, under the care of the late Dr. Hilton Fagge, on February 21, 1883, and was transferred to Dr. Taylor's care with the Clinical wards on April 1st. The following history is from the notes of Mr. S. Worthington, M. B. and Mr. H. H. Wright.

The patient is a bricklayer, and has enjoyed very good health, the only illnesses that he remembers being gonorrhœa 30 years ago, and a strain in the right side, which happened 4 years ago, and was followed by diarrhœa for 6 weeks. He has been a heavy drinker. He dates the present illness from October, 1881, when he got thoroughly wet through and subsequently drunk, so that he was a long time in his wet clothes. Though not apparently much worse for this at the time, he has ever since been getting weaker and thinner, and unfit for a day's work. In August, 1882, he first noticed the jaundice, which was not very intense at first, but has continued with variations ever since, on the whole increasing. During August, he also had epistaxis; he gave up work, went to Bournemouth, and then first felt pain between the shoulders and across the loins. Piles troubled him about the same time. For two months he had much itching, but this has been lately less troublesome: the urine is now less dark-coloured than it was; the bowels have been generally rather confined, and clay-coloured. He has had no indigestion or morning sickness. He gained a little weight at Bournemouth, but the last month has had a bad cold, and has been suffering from shortness of breath.

On admission:—He looks worn and thin; he is jaundiced, but not intensely. There is no itching, no xanthelasma, no œdema. The tongue is moist, with a whitish fur, especially at the edges. Appetite fair, but he cannot eat much meat, and has a distaste for fat. He is thirsty. The bowels act every other day; motions clayey. Abdomen rather large and rounded; the walls rigid; subcutaneous veins enlarged; no evidence of ascites. Hepatic dulness extends from the 6th rib to 1½ inch below the ribs in the mammary line, and in the middle line halfway to the umbilicus. The liver cannot be felt. Splenic dulness extends to the 12th rib. There is no pain or tenderness. He has a slight cough, with frothy, watery sputum; the chest sounds appear quite normal. The heart's impulse is forcible and diffused, and the second sound is accentuated in the pulmonary area. There is no murmur; radial arteries hard and tortuous. P. 88. Urine clear, brown, containing bile pigment, and giving a purple or lake tint with Pettenkofer's test. No sugar, a small quantity of albumen and a few blood discs. He was troubled with headaches at first, but is less so now; he has pains between the shoulders, and in the loins. He is depressed, and melancholic, attributing his present condition to his past excesses; he usually answers intelligently, but now and then makes an irrelevant remark. T 101·2°. Ordered Bicarbonate of Soda, and Succus Taraxaci.

February 23rd. The motions this morning contain no bile, but a large amount of fat. During the next few days it was made out that the liver dulness extended to the umbilicus, and it was tender on pressure; the abdomen also contained a little fluid, and measured on the 28th, 31¾ inches. The urine was passed frequently at night, and contained a few broken pigmented casts, and a few blood discs. The temperature was constantly high, from 99° to 101° in the morning, and from 101° to 103° in the evening.

During the month of March the symptoms varied a good deal. The tenderness over the liver disappeared and he became less jaundiced. The motions appeared to contain bile on the 2nd; on the 12th they contained no appreciable amount: but on the 22nd he was seized with abdominal pains, diarrhœa and vomiting; and on the 28th, it is noted that the motions contained the full complement of bile. The urine became a little less icteric, but a trace of albumen persisted; the ascites became more evident. On March 12th a very hard and distinct nodule was felt, about three inches directly to the right of the umbilicus.

On April 6th, fresh symptoms developed. He complained of pain in the left side, and on examination there was found a loud pleuritic rub below and outside the left nipple; and posteriorly below the scapular angle on the same side, dulness, feeble breath sounds and absence of tactile fremitus. On the following day there was faint bronchial breathing over the same area; and on the 8th a pericardial rub was heard over the whole præcordial area. There was scarcely any pain in this region. This rub was no longer heard on the 12th, but the heart's beat was very forcible. He was ordered Quinine mixture, and Dover's powder at night. During the rest of this month dulness and faint bronchial breathing continued at the left base, but the pleuritic rub gradually diminished. The patient became thinner and weaker. The jaundice and the condition of the liver remained much as before; the former was always present, but seemed to vary much in intensity from day to day. During May he had pain over the abdomen from time to time; he slowly emaciated. He was subject to various mental delusions, and passed his motions under him. Throughout, his temperature had been above normal, ranging between 99° and 102°, and generally about two degrees higher in the evening than in the morning. On May 29th he had a sort of fit; he was noticed to be drowsy and apathetic about 8 p.m., and half-an-hour later he was comatose with stertorous breathing, and the jaundice assumed an earthy tint. He continued so about an hour, and then slowly rallied, putting his hand to his head, and rolling his eyes from

side to side. He had at the same time marked Cheyne-Stokes respiration. The following morning he was dazed and stupid; passed urine and fæces into the bed. On the 31st he had a second fit, with convulsions of the whole body, the mouth being drawn to the left. This was followed by coma, from which he recovered in about 20 minutes, remaining, however, quite demented.

June 2nd. A little more sensible, but his mind soon fails him on talking. About 2 ounces of blood passed from his bowel. June 8th. Another fit to-day: he is more jaundiced. He has pain in the right shoulder, and the right arm is weak. June 10th. Moribund: another convulsive attack this morning. Death at 1 p.m. For several days his voice has not been strong enough for bystanders to understand, but he spoke to the Clinical assistant three hours before his death. The temperature was pyrexial till June 7th, when it fell to subnormal and remained so till death.

The *post-mortem* examination was made by Dr. Goodhart. Much emaciation, deeply jaundiced, olive-green brown. *Brain*, 56 ounces. Excess of fluid on the surface and in the ventricles. Numerous yellow tubercles spread up from the Sylvian fissures over the membranes on the outer side of the hemispheres to the cortex. Extensive meningitis of the base extending into the Sylvian fissures, particularly on the right side and at the hinder part of the right Sylvian fissure. *Lungs:* Recent pleurisy at left base. Both organs studded throughout with small nodules of clustered tubercle, stained yellow with bile. The upper lobes were most affected, and the disease spread more down the anterior borders, where there were masses of considerable size, presenting on section the appearance of caseous pneumonia, and softening into cavities. Two patches of this kind were adherent, one on each side, to the pericardium itself. *Heart*, healthy. The pericardium was toughly adherent all over. On both surfaces a layer of tubercles in the subpericardial tissue, growing still as tubercles with vascular zones around them, but tending to form a thin plate or layer all over the affected surface. *Peritoneum:* A few tubercles on the surface of the spleen and liver, and many on the diaphragm. The *small intestine* contained tenacious mucoid matter, giving no reaction with nitric acid. *Liver:* Capsule adherent to diaphragm; colour, dark olive-green. Texture not noticeably altered, and no appearance whatever of cirrhosis. No marked dilatation of any of the smaller bile ducts, that is to say, no cavities in the liver. But all through, the main ducts were thick and had a good deal of œdematous connective tissue outside them, perhaps in excess. In the left lobe these showed as dilated ducts at the thin edge of the liver, and looked at first like lymphatics, but they contained a glairy mucus, and a probe passed easily from them into the larger ducts. The main ducts were thick, and contained a thin mucoid fluid, which gave a slight reaction to nitric acid. The common duct was dilated from the junction of the two hepatic ducts, in the portal fissure to its termination. It was quite an inch in diameter. At the upper end it had a saccular form and looked scarred, as if a stone had lain there and perhaps produced ulceration. In the last half inch of the dilated duct was a large gall-stone; and the orifice was stretched over this, and exuded some bile-coloured muco-pus on pressure. The wall of the duct was thick, like an aorta. The gall-bladder was closely contracted upon three facetted gall-stones. One of these had set up inflammation of the fundus, with adhesion to the colon, which presented a ragged ulcer at this spot perforating the gall-bladder.

Kidneys:—One or two small tubercles in the cortex; otherwise healthy. *Spleen*, 15 ounces, many yellow tubercles. *Pancreas*, rather small, tissue normal, duct not dilated.

Remarks (by Dr. Taylor).—The case forms an exception to the general rule, that long-continued obstructive jaundice in old people is due to cancer of the bile ducts. This, indeed, was the diagnosis first made; and there was little to contradict this view of the case. He had some tenderness, but no local pain; and the absence of definite tumour was explained by assuming it to be in the portal fissure, the mass which was occasionally felt being, no doubt, the gall-bladder with its contained stones. The detection of a certain amount of ascites, was again in favour of a tumour in the portal fissure. This fluid seems to have been absorbed before death. On the other hand, the jaundice and the colour of the urine and fæces varied from time to time, and this would militate against the view of a persistent cancerous obstruction. But even now it is remarkable how any bile passed by the large gall-stone found in the duct. The severe radiating pain of ordinary biliary colic he seems never to have had, but only such slight pains as might be due to more common ailments. Another interesting point is the ulceration of the colon, into which part of the bowel no doubt the gall-stones would have been discharged, had he lived a little longer. One may ask whether his jaundice would not then have been cured by the establishment of a free exit for the bile. Unfortunately this was prevented by the progress of an entirely distinct pathology, namely, general tuberculosis. The first physical evidence of this appeared two months before death in the simultaneous pleurisy and pericarditis; but there can be little doubt now that his uniformly pyrexial state was due to the tuberculosis, and the cough and shortness of breath noticed before admission were indications of the same. It is surely rare that a patient with tubercular meningitis is conscious enough to speak three hours before death.

UNIVERSITY COLLEGE HOSPITAL.

SQUAMOUS EPITHELIOMA OF LOWER JAW—EXCISION—RECOVERY.

(Under the care of Mr. CHRISTOPHER HEATH.)

ALEX. D., æt. 56, was admitted on October 29, 1883.

History.—Patient is a married man, and has four children alive and healthy. He has always had sufficient food and clothing. Has had typhoid fever, and for a short time was a little out of health from overwork, otherwise has never been ill. There is no history of cancer in his family, nor of tumours of any kind. Patient has never smoked much.

Present Illness.—He first noticed a swelling on the left side of his face four months ago; he has suffered from toothache a good deal, and has lost all the teeth behind his lateral incisor on that side, and all those behind the canine on the right side. When first noticed, the tumour was about as large as a small walnut; it was situated near the angle on the left ramus; it was neither painful nor tender; it has steadily increased in size. Since the growth appeared he has had earache; it has in no way interfered with mastication.

Present State.—On the left side of the face is a rounded swelling with a smooth surface, which extends from the middle of the vertical ramus of the jaw above, to the level of the hyoid bone below; forward to the symphysis nearly. The angle can be felt distinctly; but its outline is rounded by the growth.

The swelling is firm and inelastic; its surface is perfectly smooth, and it is firmly fixed to the jaw. The growth projects into the mouth as a large, red, roundish

mass, with the surface flattened, and sloughy ; it reaches as far back as the vertical ramus, and encroaches about one-third of an inch into the floor of the mouth. There is now at times an aching pain ; but no shooting pains have been experienced.

November 1.—The patient being under chloroform, Mr. Heath made a vertical incision through the lower lip in the middle line, and another at right angles extending to the angle ; the flap was then detached from the tumour and turned upwards ; he then sawed through the jaw between the right canine and incisor teeth ; separated the tongue attachments and other soft parts inside and outside the mouth, and then disarticulated the diseased half, nipping off the tip of the coronoid process with forceps. There was not much bleeding ; each vessel was tied as it was cut. Iodoform was well rubbed in, and the wound sewn up. Two hare-lip pins were put in to close the vertical incision through the chin. Iodoform and salicylic wool were used for the dressing. For some hours after the operation, the patient could not swallow, and he was given enemata.

Examined microscopically (by Mr. Horseley), the growth was found to consist of a fibrous stroma, in which numerous leucocytes and spindle cells could be seen scattered about ; also large columnar masses of squamous epithelium cells, many of which were collected into "birds'-nests" groups.

November 4.—Hare-lip pins removed ; the wound, both inside and outside the mouth looking well.

November 7.—Was a little "off his head" last night, and tried to dress himself. He appears all right at present. Temp. 101°. Urine Sp. Gr. 1·015. No albm. No sugar.

November 8.—Again rather delirious during the night. He is being fed through an india-rubber tube, and keeps his food down well. The wounds are looking healthy.

November 27.—The patient has been steadily progressing up to this date ; the wounds are nearly healed ; he can take both fluid and solid chopped-up food without much difficulty. The man's general condition is very satisfactory. He was discharged.

Remarks by Mr. Heath.—Epithelioma occurs in the lower jaw in two forms, the columnar and the squamous. Columnar epithelioma occurs in connection with multilocular cysts and with single cysts, as was first pointed out by Mr. Eve, in his lectures at the College of Surgeons last year. Squamous epithelioma is the more common form of disease, and is found both in connection with ulceration of the gums and as a tumour of the jaw. The general characters of squamous epithelioma are well seen in the foregoing case. Rapidity of growth, with destruction of the bone and fungation into the mouth, are the leading characteristics, and nothing but early and free removal offers any chance of relief. In the above case the jaw in its upper part was apparently healthy, but I had no hesitation in disarticulating so as to be thoroughly beyond the disease, and I also went well into the healthy bone at the point of section, so as to avoid as far as possible all risk of recurrence.

A Pocket Picric Acid Test Case.—Messrs. Hawksley have devised, and are about to introduce to the notice of the profession, an apparatus for applying the picric acid test, which might almost be called a waistcoat pocket urinary test case. It consists of a graduated test tube, holding two small phials filled respectively with picric acid and fragments of potash, each fragment weighing a grain. The whole is enclosed in a cylindrical leather case. The use of picric acid in testing for albumen, and of picric acid and potash for the quantitative estimation of sugar in urine, is now so well known to, and so thoroughly appreciated by, the profession, that the usefulness of this new appliance will be generally admitted.

EAST LONDON HOSPITAL FOR CHILDREN.

ENTERIC FEVER—FALL OF TEMPERATURE ON THE NINTH DAY—RELAPSE—RECOVERY.

(Under the care of Dr. EUSTACE SMITH.)

A little girl, aged nine years, was perfectly well on September 14th. On the following day, the 15th, she complained of chilliness and frontal headache. That night the skin was noticed to be hot, and for the next week the child was apathetic, languid and feverish, complaining of headache and abdominal pain. She did not vomit and there was no bleeding from the nose. The child was seen on the 22nd ; her temperature was then 102°, and a rose spot was noticed on the abdomen by Mr. Scott Battams, the house surgeon. On the 23rd (ninth day) she was admitted into the hospital. The abdomen was then moderately distended ; the spleen could be felt two fingers' breadths below the ribs ; no spots were seen ; the temperature in the evening was 102·6°.

After this date the temperature was never higher than 99° and a fraction ; the child looked and expressed herself as well ; the spleen quickly retired under the ribs ; the appetite was good and the patient complained much at being restricted to liquid food. On October 5th, the temperature having been normal for twelve days (with the exception that on one occasion, in the course of September 27th, it rose to 111·3°) and subnormal for six, the child was put on ordinary diet. Two days afterwards the temperature rose to 102°, the spleen began to enlarge, rose spots appeared upon the abdomen, and the patient passed through a well-marked relapse of typhoid fever, which lasted nine days.

Remarks :—It is well known that in children enteric fever often assumes a mild type, and soon comes to an end. It is common for the temperature to become normal at the end of the second week ; and during the course of the illness, although the fever is high, the general symptoms are insignificant, and little distress is manifested by the patient. It is, however, exceptional for the temperature to fall as early as in the present instance. The pyrexia ceased on the ninth day, and the child seemed so well that a meat diet was allowed, under the idea that our first impression of the disease had been a mistaken one. The prompt occurrence of a typical relapse, however, at once removed our doubts as to the nature of the primary attack.

South London School of Pharmacy.—The following prizes were awarded to the successful competitors at the School examination terminating the 7th December, 1883, and presented on the 21st ultimo :—Senior Chemistry—Mr. Burford (medal), Miss Flora Mitten (certificate) ; Junior Chemistry—Mr. Williams (medal), Mr. Heaver (certificate) ; Botany—Mr. Wilkinson (medal), Mr. Burford (certificate) ; Materia Medica—Mr. Heaver (medal), Messrs. Williams and Wilkinson (equal) (certificate) ; Pharmacy and Dispensing—Mr. Heaver (medal), Mr. Turner (certificate). Extra certificates were gained by Messrs. Dutton, Hall, Taylor, and Pomeroy.—Ed.

Glasgow Fever Hospital.—A fire broke out on Tuesday last in the above institution. The roof of the laundry, which was connected with the main building, was destroyed, but the flames were quickly extinguished, and although considerable alarm was felt among the officials and patients of the hospital, it was not found necessary to remove any of the latter.

Medical Times and Gazette.

SATURDAY, JANUARY 5, 1884.

A MOVEMENT has for some time been on foot in the profession, originating with the members of the British Medical Association, for the purpose of founding a society for mutual assurance against sickness. The machinery of the Association, with its branch organization, evidently affords a highly valuable means for carrying out such an organization effectually. A similar attempt was made many years since, and not altogether without success, but at that time the organization of the Association was much less extensive than it is now, and the number of members belonging to it comparatively limited; nevertheless several hundred persons joined, and though the society ultimately came to an end, it was rather from inanition than from any other apparent cause. The claims made upon the funds were very few, and adequate means do not appear to have been taken to make the operations of the society continuously well known, and to keep it in active operation. In the end the whole of the funds were returned and no loss was incurred by the subscribers.

DEMANDS for the re-formation of such a society have been repeated for many years, and the project, we are glad to see, has at last taken definite shape. A meeting in connection with it was held, it will be remembered, during the last annual session of the British Medical Association at Liverpool, and documents were presented, showing the written adhesion of upwards of 600 members of the Association to such a society in principle. A provisional committee has been formed, tables have been constructed by Mr. Neison, which include not only temporary and permanent sick pay, but also other benefits such as are usual among Friendly Societies, viz., limited life assurance, and permanent annuity after a certain age. Copies of the draft rules and tables will be found in our advertisement pages, and in view of the constant and repeated applications for charity owing to the breaking down in health of the members of the profession in limited practice, as well as in consideration of the hardships and sufferings that many have to undergo, owing to the loss of income incurred during severe illness, and the absence of means to provide a *locum tenens*, it is to be hoped that the society may be conducted to a successful end, and may cover a large surface in the profession. It appears to be based on a principle of providence which cannot be too strongly encouraged, and if successful, as in the opinion of high actuarial authorities it may fairly be expected to be, such a society will obviously confer a great boon on the profession, and its organizers will be deserving of all gratitude.

THE *Scotsman* of Friday last published an able article on the episodes of interest to the Medical Profession which occurred during the past year. It remarks on the deserved honours profusely showered on its leaders by the State with one hand, while with the other it has dealt blows of the most fatal character against the responsible body of general practitioners. Speaking of the political powerlessness of the profession, it holds that in these days of sanitary reform the men who should most naturally be looked to for taking a leading part in the direction of affairs, and in the formation of a healthy public opinion, are those who, alike from their training and their daily duties, are capable of appreciating the surroundings of the poor and of gauging the difficulties of their lot. Whether in imperial or local politics, the influence of men of scientific training is much to be desired, and in the future must have a wider application than in the past.

CONTRASTING the higher honours conferred on successful generals with the treatment of men of science, the *Scotsman* considers it anomalous that a man like Parkes, whose life-work was devoted to the beneficent end that armies might be kept safe from outbreaks more fatal in war than shot or shell, should go to the grave scarce noticed by the country he had served so well, and that Farr, the founder of the science of vital statistics, whose generalizations are now accepted maxims in dealing with the health problems of dense populations, should, after a life of drudgery at the desk, sink under the weight of years, leaving those nearest and dearest to him dependent on others, while the State and the world continue to profit enormously by his unrequited services. But it also acknowledges that distinctions conferred by the State are not the goal towards which our noblest minds strive, and that the love of truth and of humanity form incentives enough for the highest work. The article concludes with an allusion to the Bower and Keates' case, and an expression of opinion that under the Scottish system such an injustice could hardly have been perpetrated. Seldom have we met with a leader in a lay paper so thoroughly sympathetic to the profession, and so generally right-thinking.

THE January meeting of Convocation of the University of London will be held on Tuesday next, at 5 o'clock. There is nothing of special interest to the Medical Faculty on the agenda.

MR. HOLLOWAY is dead, and the papers have been full of moralizings on his career. There is doubtless a lesson to be drawn from the life of every successful man, and the one who wins his success by playing on the foolishness and credulity of his kind is an object especially worthy of meditation. His prosperity leads one to realize the low average of human intelligence, and tends to check over-weening conceit in one's own powers, just as the sight of a successful conjuror depresses one's estimate of one's own acumen. It is related that Gargantua was taken by his sagacious tutor "to see jugglers, tumblers, mountebanks, and quacksalvers, to consider their cunning, their shifts, their summersaults and smooth tongues, especially those of Chauny, in Picardy, who are naturally great praters, and brave gibers of fibs, in matters of green apes." Mr. Holloway, we are informed by a correspondent, was a great

hypochondriac. In his earlier days, when he lived over his pill-shop in the Strand, he often consulted Mr. Digby, a well-known practitioner of the neighbourhood, whose remedies, we are told, he invariably preferred to his own.

Mr. Holloway will be chiefly remembered as the man who first conceived the possibilities of fortune which lie in the modern development of the advertising system. It needed a certain kind of genius to see that; and he has shown the same grandeur of conception in the two remarkable institutions to which he has devoted such a large part of his fortune. But the moral of his life is not a wholesome one. It is sufficient to tempt unstable minds astray. It is not pleasant or encouraging to the medical practitioner, who, after a life of incessant but honourable labour, barely manages to provide for his family, to see a seller of quack medicines ranking among the richest millionaires in the world. Holloway's success and that of his imitators has not had a good effect on the medical profession, and if there is no open advertising by medical men, there is more than enough of advertising under the rose. There are men amongst us—not greatly respected, it is true—who manage to advertise themselves in almost as many newspapers as Holloway, and without paying a sou; but, happily, we have not heard that they have secured any share of his marvellous success.

The Epidemiological Society will, on Wednesday next, have what by a strange confusion of language it is customary in medical journalism to call a "field-night." Surgeon-General Hunter is to read a paper on the origin of the Cholera Epidemic in Egypt, which will, no doubt, excite much discussion. It is important that the subject should be thoroughly debated, as the future action of our Government in Egypt, at any rate in a sanitary direction, will depend on whether Surgeon-General Hunter is considered to have proved his case or not. If his view is accepted, that cholera has been endemic in Egypt for years, the Government, we believe, are prepared to take energetic steps to improve the sanitary condition of the country, in spite of all opposition. But anything short of conclusive demonstration would doubtless lessen their feelings of responsibility in the matter. The meeting of the Epidemiological Society will henceforward be held on the *second* Wednesday in each month, and in Chandos-street instead of at University College.

When the time comes—if it ever does come—for the Sanitarian to begin work upon the Augean stable of Egypt, one of the first things to which he will have to direct his attention will be the domestic cesspool. It is customary, even in the largest houses in the chief centres of population, for this necessary receptacle to be placed in the very centre of the dwelling-room, where the males of the family live together with their retinue of camels, goats, and donkeys. Once a day, the slab which covers, if it does not conceal, the cesspool, is rolled aside, the accumulated excrement of the twenty-four hours, human and animal, is thrown in, and the slab rolled back again. From time to time the cavity is emptied, and its contents are heaped up in a convenient spot to dry, and serve for future fuel. The Englishman holds up his hands in horror at the existence of such a state of things; but let him compare it for a moment with what Dr. Barry found at North Shields, when he went last summer to report upon the sanitary state of that locality.

North Shields, it may be stated for the benefit of those who are not familiar with the geography of those parts, is hard by Tynemouth, the favourite watering-place and health-resort of the dwellers in the populous Newcastle district. The lower part of the former town was built at a time when all traffic was carried on by means of packhorses, and therefore the streets which run from end to end are exceedingly narrow. Lanes and courts branch off from them at right angles, to be terminated on one side by the river Tyne, on the other by the cliffs. In these side streets the entire houses are divided off into tenements, frequently inhabited by the poorest and most degraded classes. The houses are often situated round close courts, and in many cases are built back to back, so that through ventilation is impossible. But even if it could be ensured, the advantage, according to Dr. Barry, would be doubtful. In many houses there is no privy accommodation, and all the refuse of every kind is thrown into the centre of the court, so that the atmosphere outside the dwellings is more noisome than that within. Dr. Barry was informed that this absence of privy accommodation had been known in some instances to lead to the deposition of all filth under the flooring, or in the cupboards of the houses. It is not surprising to hear that these sanitary conditions have markedly influenced the mortality in North Shields, the Medical Officer of Health reporting in his summary for 1882, that the death-rate for the township had reached as high a figure as 30·4 per 1,000 living. Dr. Barry admits that the Sanitary Authority of the district have devoted considerable attention to their duties. They have enforced the supply of wholesome water, have attended to sewerage and drainage, undertaken the removal of refuse, and provided an ample supply of sea-water for public and private use. But he says, and probably with justice, that much yet remains to be done, in order to deal with the various defective conditions above noted, which do not indeed appear to be very greatly superior to those which prevail in cholera-smitten Egypt. Surely sanitation, like Charity, should begin at home.

In America, coca is now prescribed with tobacco for "chewers." A combination "plug" of coca and tobacco is extensively advertised in the St. Louis papers, and certificates from prominent physicians are quoted to the effect that tobacco *plus* coca is less injurious to the system than is tobacco alone.

A Correspondent, signing himself "M.R.C.P.," has sent us the following extract from an American journal, which bears evident signs of having been written by a man thoroughly conversant with his subject:—

"The social position of the whole medical profession in England is much lower than it ought to be. The distinc-

tions lavished on other professions are very rarely conferred on medical men; but the profession has itself to thank to a great extent for this difference. The amount of gratuitous work done by the profession in no way raises it in the public esteem. It is well known that it is not performed from motives of charity, but for the position which is gained by being attached to a hospital staff, and the hopes of a good practice ultimately accruing therefrom. This custom of gratuitous services to the hospitals has grown on the profession, and many a young physician and surgeon now is exhausting himself in mind and body by attending gratuitously at hospitals patients whose incomes are in some cases much greater than his own. This injustice the public, as represented by the people who support the hospitals, in no wise wish; they would be quite willing that the first charge on the incomes of the hospitals should be to adequately remunerate the medical men who attend upon the sick. But any reform in this direction must emanate from the heads of the profession. No profession can be expected to rise in social position when kept in a state of penury; and this poverty-stricken state of the medical profession, as it is in England, is a great deal due to the action of those who hold the highest position in it. They preach to the younger members, who are getting nothing from their hospital appointments, to keep up the dignity of the profession by never taking from a private patient less than their guinea or two guinea fee, when the same patient can see men of the greatest reputation and obtain their advice for the same amount. The senior men with high reputations ought never to take less than five or ten guineas; there would then be a chance of the junior members of the profession sometimes obtaining a patient. One of the by-laws of the Royal College of Physicians of London is, that 'No fellow or member of the college shall officiously, or under colour of a benevolent purpose, offer medical aid to, or prescribe for, any patient whom he knows to be under the care of another legally qualified medical practitioner.' The spirit of this by-law is being constantly broken, for medical aid and advice is often given by the best physicians and surgeons in London to patients who they think cannot pay their fee, but could easily pay the fee of a general practitioner; and while acting as they think benevolently to the one they are depriving the other of his due, and thereby lowering the status of the profession. In the out-patient departments of our hospitals this injustice is carried to an extreme, and the rank and file of our profession have ample cause for the bitter complaints they level at the London consultants. The elevation of the profession in the social scale is entirely in the hands of those who are called 'the heads of the profession,' and any inferiority under which it may suffer is entirely due to their action, and for it they may be considered responsible. Large incomes in England are made by about ten or a dozen of the leading medical men, and these are not so large as they ought to be. The rest of the profession is in a miserably under-paid condition."

"M. R. C. P." suggests, as a remedy for this state of things, an entire revision of the fees chargeable by consultants, and he recommends the following table as likely, if adopted, to meet the difficulty:—

Table of Fees for Consultants.

	Consultation from home.	Consultation in own rooms.	If in regular attendance (each visit.)	Operations.	Midwifery.
	£ s.	£ s.	£ s.	£ s.	£ s.
No. 1.—Titled Physicians and Surgeons	10 10	5 5	3 3	52 10	52 10
No. 2.—Senior Physicians and Surgeons of Hospital Staffs	5 5	3 3	2 2	25 5	26 5
No. 3.—Physicians and Surgeons of established reputation	3 3	2 2	1 1	15 15	15 15
No. 4.—Junior Physicians and Surgeons	2 2	1 1	1 1	10 10	10 10

All the above fees chargeable in London; or in the town where the consultant may be resident.

Additional fees for distance beyond four miles from Charing Cross, or from the centre of any provincial town.

No. 1.—A guinea a mile (*e.g.*, 60 miles, 60 guineas).

No. 2.—Two-thirds of the distance in miles in guineas (*e.g.*, 60 miles, 40 guineas).

No. 3.—Every three miles, a guinea (*e.g.*, 60 miles, 20 guineas).

No. 4.—Every four miles, a guinea (*e.g.*, 60 miles, 15 guineas).

"M. R. C. P." thinks, that "when once the consultants appreciate their position, and the public have learnt to estimate their assistance at something much nearer its proper value than at present, we may hope to improve the social position of the profession, and to raise in many respects the incomes of the general practitioners; and especially to demand from the State that those medical officers who treat the sick poor in the parishes throughout the country, shall be fairly remunerated."

Our own feeling in this matter, which will be admitted to be one of the first importance, is that the whole difficulty is due to the overcrowded state of the consulting branches of the profession, and the remedy is to be sought in a gradual increase in the dignity and attractiveness of the general practitioner's life. The fees charged by senior consultants might, no doubt, be raised with advantage, and we are glad to hear that one titled practitioner at least is now charging three guineas for every first consultation at his own house. But it must be remembered that each rise in fees would tempt more and more young men to become consultants, and there would soon be as great a struggle for patients as there is at present. In spite of the multiplication of hospitals, there has never before been anything approaching the competition that there is now for hospital appointments, and the scramble for insurance vacancies is little short of ludicrous. What the consulting branches want, to restore to them a healthy tone, is a little depletion, or rather a good deal of depletion. If fifty of the youngest consultants would make up their minds to sacrifice their dignity, learn a little midwifery, and settle down as general practitioners in the best neighbourhoods in London and the chief watering-places, they would find themselves in ten years making incomes that not more than half a dozen of them will ever probably make under existing circumstances, and those they left behind would see some semblance of hope beckoning to them in the future. Science would lose, no doubt, by it, but the general sum of happiness would gain.

The new number of the *Medical Directory*, which has just been issued, shows a quite unusual increase in the members of the profession: there are nearly eleven hundred more names in the present volume than in last year's Directory; the reason for this exceptional recruitment evidently being that large numbers have made haste to qualify themselves before the threatened legislation makes qualification more difficult. The total number of practitioners in the new Directory

is 25,038, divided as follows :—London List, 4,417 ; Provincial List, 11,775 ; List for Scotland, 2,206 ; List for Ireland, 2,430 ; Registered Practitioners Resident Abroad, 1,717 ; Army, Navy, Indian Medical Service and Mercantile Marine, 2,493.

The Navy Medical Blue-Book for 1882 has just been published—too late, however, to allow us to notice it at length. The sick-list returns, the invaliding-rate, and the death-rate from disease, all show a slight increase on the figures for 1881. Some of this increase is accounted for by the sickness and casualties consequent on the Egyptian War. But in addition to this, there was on the Home Station more enteric fever than usual ; on the Mediterranean Station there was a serious epidemic of remittent fever, caused by local conditions at Malta ; at Port Royal, Jamaica, there was an outbreak of yellow fever ; and in the East there was also an unusual amount of sickness from febrile affections. Still a death-rate from disease of only 6·87 per 1,000 cannot be regarded as very unsatisfactory.

At its recent annual meeting, the Paris Academy of Medicine announced the names of the successful competitors for its prizes in 1882 :—1. The Academy Prize for the question "Generalised Arterial Atheroma, and its Influence on the Nutrition of Organs" was adjudged to Dr. Hippolyte Martin, Chief of the Clinical Laboratory of the Diseases of Children. 2. The Portal Prize, "The Lymphatic System from a Pathological Point of View," to Dr. A. Poulet, *Agrégé* Professor at the Val-de-Grâce. 3. The Civrieux Prize, "The Causes of Locomotor Ataxy," to Dr. Landouzy, *Agrégé* Professor of the Faculty of Medicine, and Dr. Ballet, Chef de Clinique of the Faculty. 4. The Capuron Prize, "The Lochia in their Normal and Pathological Conditions," to Dr. Eustache, of Lille. 5. The Barbier Prize was not awarded, but an "encouragement" was given to Dr. Willems, of Hasselt (Belgium), for his works on the "Inoculation of Pleuropneumonia." 6. The Godard Prize was divided between Dr. Leloir, for his "Clinical and Anatomo-pathological Researches on Cutaneous Affections of Nervous Origin," and Profs. Feltz and Ritter, of Nancy, for their work on "Experimental Uræmia." Honourable Mention was also awarded to Dr. Borius for his work on the "Diseases of Senegal," and to Dr. Ballet for his "Clinical and Anatomical Researches." 7. The Itard Prize, for the best work on Practical Medicine or Applied Therapeutics, which had been published at least two years previously, was divided between Dr. A. Poulet, for his "Treatise on Foreign Bodies in Surgery," Dr. Sanné for his "Traité de la Diphthérie," and Dr. Latteux for his "Manual of Microscopical Technics." 8. The Falret Prize, "Vertigo with Delirium," to Dr. Garnier, Inspector of Lunatic Asylums. 9. The St. Paul Prize, for a sovereign and efficacious Remedy for Diphtheria, was not adjudged, but an "encouragement" was awarded to Dr. Leloir for his "Contribution to the Study of the Structure and Development of Pseudo-membranous Productions on the Membranes and Skin." For several other prizes there were no candidates.

The announcement of the prizes in the *Bulletin* of December 18 is preceded by an interesting report by the Secretary to the Academy, Dr. Proust, recapitulating the views which have guided the adjudicators in their reports upon the essays submitted to their notice ; but for this we have not space. The prize-questions for the year 1884 are as follows :—The Academy Prize of 1,000 frs., "The presence of Bacilli in the Sputa, and their Semeiological Value." 2. The Portal Prize of 1,000 frs., "The Pathological Anatomy of Cancers." 3. The Civrieux Prize of 1,500 frs., "Sclerosis in Dis-Pseminated Patches." 4. The Capuron Prize of 1,500 frs., "Traumatism and Pregnancy—their Reciprocal Influences." 5. The Barbier Prize, of many thousand francs, is offered for the discovery of a complete cure of diseases usually regarded as incurable, as hydrophobia, cancer, epilepsy, scrofula, typhus, cholera, &c. ; but awaiting this, "encouragements" are to be given from the interest of the money (3,000 frs. in 1884) to those who, without attaining this aim, have approached it most nearly. 6. The Godard Prize of 1,500 frs., for the best work on Internal Pathology. 7. The Desportes Prize of 1,500 frs., for the best work on Practical Medical Therapeutics. 8. The Buignet Prize of 1,500 frs. to the author of the best work, printed or in MS., on the application of Physics or Chemistry to the Medical Sciences. 9. The Daudet Prize of 2,000 frs., "Lymphadenoma." 10. The Vernois Prize of 800 frs. is offered for the best work on Hygiene. 11. The Lefevre prize of 2,500 frs. will be given to the author of the best work on Melancholia. 12. The Falret prize of 1,000 frs. "Diathetic Insanity." 13. The Orfila Prize of 6,000 frs., "Veratrine, Sabadilline, Black Hellebore, and White Veratrum." 14. The Prize of the Committee on Infantile Hygiene, of 1,500 frs., for "The Etiology and Prophylaxis of Scrofula in Early Infancy." 15. The St. Lager Prize of 1,500 frs. is to be awarded for the experimental production of a tumour of the thyroid by the administration of substances extracted from the waters or soils where goitre is endemic. 16. The St. Paul Prize of 25,000 frs. for the discovery of a certain cure for diphtheria—the interest of the prize-money being employed in remunerating those whose researches on the subject are meanwhile approved of. The essays and works competing for these prizes, written in French or Latin, must be delivered at the Academy before the 1st July, 1884. None of these will be returned ; but copies may be made at the expense of their authors at the Academy.

M. Alphonse Guérin has been elected President of the Academy for 1884, and Dr. Fauvel Vice-President.

Yet another advance in abdominal surgery. In the second number of the *Bristol Medico-Chirurgical Journal*, Mr. Nelson Dobson suggests the propriety of opening the abdomen in cases of perforating ulcer of the stomach. The case which brought to his mind the desirability of seriously considering the propriety of this step, was that of a young woman (aged 27), who after a rather laborious day, had been seized with faintness and pain in the abdomen. When seen after the lapse of three hours there was collapse, with pain at

the epigastrium and general abdominal tenderness. Death with symptoms of peritonitis took place in less than twenty-four hours. At the necropsy a hole was found in the anterior wall of the stomach, a situation, as Mr. Dodson points out, readily accessible to an operator. We have so recently, in one of our clinical papers, insisted upon the importance of recognising the diagnostic symptoms of gastric ulcer, that we need not reiterate them. A careful attention to the history of the case would, in most instances, enable a correct diagnosis to be made. Having decided to operate, Mr. Dobson points out that three courses are open to the surgeon: he may content himself with sponging out the peritonæal cavity, and trust to time to heal the ulcer whilst he feeds the patient by means of enemata; or he may bring the edges of the ulcer together with sutures, with or without paring them; or he may stitch the stomach to the abdominal wall and establish a gastric fistula. The last proposal does not commend itself to us, unless perhaps for exceptional cases; nor do we think that to pare the edges of the ulcer would be a prudent proceeding, when we recollect that it might be followed by bleeding into the stomach, which, even if recognised in time, might be difficult to control. On the whole we would prefer to trust to time, and to keeping the patient's strength up by nutrient enemata. We consider Mr. Dobson's idea quite within the bounds of practical surgery, and hope some day to be able by its means to record that a life or lives have been saved.

On Saturday last Earl Stanhope presided at the tenth annual meeting, at Sevenoaks, of the Holmesdale Cottage Hospital. During the past year the hospital has been enlarged, and the committee were able to present a very satisfactory report. To the vote of thanks proposed to the consulting and ordinary staff, Mr. LeGros Clark, the honorary consulting surgeon, replied.

The good Catholics of Paris are advised by their Archbishop to "boycott" the hospitals. The priests are no longer allowed to reside in them, or to visit them at all, unless sent for, and though the Archbishop has provided a special staff of priests for hospital work, the Government will not pay them. He therefore beseeches the faithful not to send the sick in their charge to the hospitals, but to organize a system whereby they can be treated at home. The feeling on this subject must, of course, be very different in a Catholic country from that which prevails in a Protestant one, where less weight is attached to death-bed ministrations; but, making every allowance, the action of the Archbishop cannot be considered anything but childish and ill-advised. A system of efficient out-door treatment is not organized in a day, even with the willing help of the medical profession, and meanwhile many hundreds of sick poor are to be robbed of the advantage of skilled medical aid, because the small percentage of them who die may find some difficulty in securing the last consolations of religion. That is, indeed, making the many suffer for the welfare of the few.

Dr. McCausland, in a communication to the *Philadelphia Medical Reporter* (Oct. 27), furnishes an account of some observations which he and another medical man have made upon a man, aged 28, from one hour before his execution by hanging up to the moment of death. He met his fate in a calm and collected manner, although he seemed to be in a kind of dazed condition, caused no doubt by his mental suffering. The muscular system was tremulous and somewhat relaxed; pupils slightly dilated; efforts at swallowing repeated twice a minute; respiration 28, inspiration being quick and spasmodic and expiration longer, and pulse 112, apparently full and bounding. A tracing was taken with the sphygmograph, which, while it showed the effects of the hot whisky punch which he was taking, in other respects was identical with the tracing of a man suffering from shock. After the trap was sprung his pulse was taken every quarter of a minute. The third quarter of the first minute it was twelve beats per fifteen seconds. It increased rapidly until the last quarter of the fifth minute, when it was thirty-eight per fifteen seconds. It now rapidly declined, or rather became indistinct until the end of the seventh minute, when it could no longer be discerned. By means of a stethoscope the heart's action was noted at the eleventh minute 120 strokes—weak and irregular—and rapidly merging into an indistinct fluttering sound, which was maintained until the end of the fourteenth minute. At the end of the fifteenth, life was pronounced extinct. There was complete dislocation of the cervical vertebræ.

The Registrar-General is an adept in the expression of sarcasm by means of italics. In his last weekly report he tells us, that in the outer ring of London there were registered during the week six cases of "fever." In the Staines sub-districts again two cases of "fever" were registered. "Pray, good general practitioners, do be more accurate," is what those dashed-in italics are meant to convey. Now accuracy in diagnosis is a good lesson to teach, and for preventive purposes, the registration of a death as due to "fever," is practically useless. But there is something to be said on the other side, and from a scientific point of view it is better for a practitioner to admit that he is unable to diagnose a case, than to assume a virtue that he does not possess for the sake of the Registrar-General. Indefiniteness in statement is sometimes a duty, and medical men are as a rule, we believe, much more likely to err in certifying to more than they know, than in candidly recording less than they know.

Except for an epidemic of falls—falls from ladders, from stairs, from chairs, from boys' backs, from scaffolds, and from other undefined elevations, most of them due probably as much to the attraction of the bottle as to that of the earth—the Christmas week of last year was a comparatively healthy one. The death-rate sank below 20—from 21·2 in the previous week to 19·8—but a little of this decline is probably to be accounted for by the reluctance to register deaths in a week of festivity, unless absolutely necessary. As, however, the number of deaths was nearly 500 below the average of the corresponding week in the past ten years, and as

one Christmas is not likely to interfere more with registration than another, it may be concluded that the week was almost as healthy as the death-rate shows. Measles and scarlet fever were again the most fatal of the zymotic diseases, and show over a hundred deaths between them; but whooping-cough, diphtheria, typhoid, and diarrhœa were all active, and accounted together for close upon another hundred of deaths. The quarter just ended, which on the whole has been remarkable for fine weather, was healthier than the corresponding period of the three previous years. The weather of its last week was, however, atrocious. Not an instant of sunshine was registered at Greenwich during the whole seven days, and Paris has not, we hear, been any luckier.

Dr. Domett Stone has recently contributed to *The Times* a letter on Ship Surgeons, in which he takes to task the Marine Department of the Board of Trade, for the *laissez-aller* it exhibits in everything connected with the mercantile marine of this great country, more especially for the apathy it evinces in the appointment of ship surgeons. "It is a notorious fact," Dr. Domett Stone writes, "as reprehensible as it is true—that thousands of emigrants leave these shores for distant parts under the impression (and, in some cases, with the positive guarantee) that, as advertised, 'an experienced surgeon accompanies the vessel,' and therefore there need be no unnecessary alarm in the event of accident or illness during the voyage." The contrary he points out is frequently the case, hence the high mortality of passengers at sea. To prevent the possibility of men unqualified in any respect, and the "ne'er-do-weels" and black sheep of the profession, obtaining such appointments, Dr. Stone suggests that the superintendents of mercantile marine who make a point of demanding from the master of any foreign-going ship his certificate of qualification, as also those of the first and second officers and engineers (if any), should also ascertain the qualification of any medical practitioner seeking employment in the service. It appears that the owners of vessels employed in the North Sea whale fishery, admit the dangerous nature of the traffic in which their ships are engaged, and therefore engage a *surgeon* (?), but it is notorious that for years past mere youths have been shipped to attend upon the crew in the event of accident to life or limb, and it is stated that two vessels sailed last year from Dundee, for the whale fishery, the ages of the *surgeons* (?) being respectively 17 and 20! That so few able men should care to become ship surgeons arises from the fact that the pay is scandalously low, less than the wages paid to the steward, and the accommodation provided scarcely fit for a dog kennel. It will be seen that, in pointing out the bane, Dr. Domett Stone has not omitted to prescribe the antidote, and he concludes his letter, which is full of sound argument and apt quotations, by strongly urging ship surgeons to at once enrol themselves into a Mercantile Marine Medical Service, and to lay their grievances before Parliament.

At the meeting of the Pathological Society this (Friday) evening, in addition to the business already announced, an address will be delivered by the President, Mr. J. W. Hulke, F.R.S.

THE MEDICAL TIMES.

"The work was commenced with a firm determination to unmask quackery, and, by upholding the honour and dignity of medicine, advance at once the wellbeing of the profession and the great interests of humanity. In this attempt we have struck at the root of the mammoth evils which, in the shape of monopoly and misgovernment, choke and almost destroy the profession, defeating the fulfilment of its brighter destiny by removing the stimulus to a high and noble exertion." These are almost the first lines in the preface to the first volume of this journal, published nearly forty-four years ago; and though other times have brought in other manners, and a cry that was not ill-suited for a new-born enterprise may well sound too youthful and ardent in the mouth of one past middle age, we are not sure that the *Medical Times* of the present day might not do worse than adopt the spirit of the policy thus expressed. Every one, at any rate, who has looked into the early volumes of this journal will admit that its policy was carried out with sufficient energy and outspokenness. The first number appeared on September 28, 1839, and was a closely-printed sheet of eight pages, soon increased to twelve. By July, 1850, when a New Series was commenced, it had increased to twenty-eight pages, and its character had grown considerably in solidity. Many of the best lectures of the time were published in its columns, Sir William Jenner's epoch-making Course on the Continued Fevers appearing in the first volume of the New Series. In January, 1852, the *Medical Times* coalesced with the *Medical Gazette*, a long-established and highly-esteemed periodical, published by Messrs. Longmans, and the combined journal then took the name under which it has so long been honourably known. Soon after the coalition, Mr. (now Sir) Spencer Wells assumed the editorship; and, except for a short period (during which he was in the East, at the time of the Crimean War), held it until press of work compelled him to retire in 1862. He was succeeded by Dr. Druitt, who in turn, after a most successful and honourable period of editorship, was, in 1870, forced by ill-health to withdraw from his post. Under these two distinguished leaders the journal gradually assumed a still more serious and scientific tone, and represented more and more the spirit of the most ardent workers and the most philosophic minds in the profession. To enumerate the authors whose lectures have originally appeared in these pages, and the writers who have at one time or another been connected with the journal, would be to give a list of many of the best known and most highly honoured names in the profession. The aims impressed upon the journal by Sir Spencer Wells and Dr. Druitt have been consistently followed by their successors; and, looking back on the last twelve years, we may say, without arrogance or exaggeration, that no medical journal in any country has been more thoroughly respected for its single-hearted devotion to the advancement of science and the welfare of the medical profession.

The above brief summary of the past history of the *Medical Times* will serve appropriately to introduce a rough sketch of the lines on which the journal will be

conducted in the future. The first aim will be to make it—what it has been in the past—essentially a clinical journal. The one permanent and absorbing interest of the average medical reader is his interest in his profession as such. Political and ethical topics ever and anon come to the front, and it is the business of the medical journalist to inform himself and his readers about them in all their bearings. It is his duty to hear all that is being said and thought respecting them by the best men in the profession; faithfully to form his own opinion, and to speak it out boldly, independently, and so far as he can without individual or class bias. On such matters we shall always endeavour to express the higher and more advanced thought of the profession, in the hope that the after progress of events will give us no cause to regret the hastiness or be ashamed of the narrowness of our judgments. But, after all, the laws regulating the relations of the members of the profession to the State and to each other, which fall broadly under the heads of politics and ethics, are but a means to an end. Their final cause is to make the daily work of the practitioner efficient, honourable, and pleasant; and, bearing this constantly in mind, it will be our effort to steer clear of the common fault of politicians and ethicists—medical or otherwise—who are apt to grow so absorbed in the object of their study, that they come to confound the means with the end, and to think that such achievements as the passing of a medical Act, the social elevation of the profession, or the formulation of a strict code of ethics are the main goal of existence, and the objects of as absorbing a passion to their brother-practitioners as to themselves. The one common interest of the medical profession is, we repeat, a clinical interest, and the highest and worthiest function of a medical journal is to stimulate and to satisfy it in all its numerous phases. The lectures, original articles, and cases which we present to the reader in this number are an earnest of the importance which we attach to this part of our *rôle*. The clinical papers—specially written by physicians and surgeons of repute—(the third of which appears to-day) are a further indication of our anxiety to furnish our readers with clinical matter worthy of thoughtful attention. Their aim is to draw on the wide experience and observation of hospital physicians and surgeons, for the benefit chiefly of those who have not their extended opportunities of clinical research. But their value will not be limited to the latter class; for, apart from the fact that honest clinical observation has its pass-key to every brain, a thoughtful mind dealing with the commonest of subjects will often show it in a fresh light, even to those whose range of experience is not inferior to his own. We shall not apologise, therefore, if some of the papers in the series deal with subjects on which some may think that the last word has been said. The Reports of Societies, which form another branch of the clinical work of medical journalism, will make their appearance promptly, and in as brief terms as is consistent with faithful rendering; while in the Abstracts and Extracts from our contemporaries in this and other countries, it will be our aim to supply the reader with a careful epitome of the progress of medical science in all its branches.

The *Medical Times* is comparatively a small journal, and that we claim as an advantage. It renders it a necessity to select only the best original articles and cases that are offered to us, it makes padding superfluous, and it is a constant reminder to the editorial staff to say all they have to say as tersely as possible. The main cause of unreadableness in a journal is not obscurity so much as diffuseness; and the small number of our pages, compared with the bulkiness of some of our contemporaries, will, we hope, result in the *Medical Times* being, as the saying is, "readable from cover to cover." The successive editors of this journal have always attached much importance to literary style, and we hope that the past reputation for restrained and cultured writing will be fully maintained. It is true, again, that style, as such, is only a means to an end, and if one has nothing to say, it is of little credit to him to have said that nothing in graceful language; but the end is often lost through want of sufficient attention to the means, and many writers, even in our profession, have failed to gain for their researches the attention they deserved, simply from their faulty method of presenting them to their readers. In these swift days men have not the time to linger over books, or find a pleasure in unravelling the mazes of obscure sentences. They have been taught to expect from those who cater for their literary instruction or entertainment, a lucid, fresh, and readable style; and though easy reading may be unconscionably hard writing, we promise that no efforts of ours shall be spared to make the *Medical Times* the most thoughtful, most suggestive, and most readable of English medical journals. As to honesty, faithfulness, and independence, we shall say nothing, except that we think them the all-important and essential attributes of a journal written by and for the members of an honourable profession.

OBSERVATION AND EXPERIMENT IN MEDICINE.

It is the proper boast of the present days of medicine that its practice is becoming more and more scientific, or, in other words, increasingly dependent on a rational inquiry into the causes of disease. No arguments are necessary now to prove the advantages of this method to the study of the functions of the human body, and the solid results which have been thus already attained; and it is obvious that the hope that we may entertain of arriving at a truer pathology and the best lines of treatment is largely proportionate to the successful pursuit of the causes of derangements of health. Fanciful superstition, and more or less ingenious guesswork raised to the dignity of a dogma, have nearly played out their part in the domain of medical investigation, or, if still more prominent than is willingly admitted, are in name at least discredited; and the methods of rigid logic based on observation and experiment are now in the ascendant, bidding fair in time to be genuinely, thoroughly, and thoughtfully followed. When this desired consummation shall have come to pass, then, and then alone, will the death-blow have been struck, not only at the fascinations of successful quackery, but also at the premature conclusions of

rash, short-sighted, and over-eager, though, up to their lights, well-meaning adherents of what they deem to be scientific method. The fallacies and pit-falls, however, which are neither few nor far between, upon the path of modern medicine, have perhaps been insufficiently present to the minds of many workers, and it is the existence and nature of some of these that we shall endeavour to point out in these remarks.

A comparison between scientific method, or the search after causes, and the demonstrated results of sufficient inquiry, or *exact science*, is at the bottom of many faulty views as to the nature of medical research, and of much incomplete and erroneous teaching and writing. It is often forgotten that a science becomes exact in proportion to the simplicity of the subject-matter with which it deals. The more obvious the fundamental facts of which we seek the causes, and the less complex their nature, so much the sooner do we arrive at accurate generalizations from them, and the more readily can we utilize them for reasonable practice. A great difference here shows itself between some of the sciences on which the practice of medicine ultimately rests, and the mass of knowledge called "medical science," which is the proper and proximate substratum of the medical art. The aim of all scientific research is to arrive at demonstration and the possibility of true prediction as to what may happen in given circumstances; and this can only be attained by a due study and questioning of nature by observation first, and, when possible, by experiment afterwards. Observation must always come first in every department of knowledge, but in order to try our conclusions, and to keep hold of that which is probable, it is indispensable to test our results by something more than merely collecting facts *ad infinitum*, unaided by a theory.

This testing, which is a necessary factor in all exact knowledge, is performed, generally speaking, by the further employment of the method of observation, rationally guided by a suggestive hypothesis, or by the application of the method of what is more properly called experimentation, or, in other words, by in some way altering, for the purpose of our inquiry, the conditions of the material we are studying. When we know enough of any one subject to apply the method of experiment aright, we arrive at demonstration in the most direct and satisfactory manner, and by what is known as an *experimentum crucis* we may attain to a finally complete answer to our questioning. In physics and in chemistry, so obviously ancillary and introductory to the study of medicine, this stage has been to a great extent reached; and by their use of the method of direct experiment these subjects may claim to be considered as exact sciences. Physiology, too, or at least some chapters of it, is now to be regarded as largely experimental, having arrived at that point where much is to be looked for from the application of the experimental method in its strictest sense. Much, however, of the still untilled field of Physiology, especially the study of purely vital action in the human subject, must perforce be worked, on account of both the confessed complexity and the peculiar exigencies of its material, by the method of observation alone, though this very observation, to be fruitful, must be carried out by the help of rational hypothesis; with, indeed, the spirit of experiment itself, when actual experiment, possible up to a certain limit, can no longer be employed.

Coming lastly to Human Pathology, or the study of diseased conditions, that subsection of Physiology which immediately underlies the rational practice of medicine, we shall find from the very nature of its subject-matter and the greatness of its undiscovered area, that we must still be largely indebted to the method of observation of disease during life, and of its possible sources and results in the body after death, for increasing knowledge and better explanation of its facts and problems. Observation, both clinical and anatomical, is daily adding to our knowledge in this department, and its conquests are great enough to bid us in no way despair of the future. A certain scope for experiment proper is apparently pointed out to us by the hypothesis now so largely occupying the minds of biologists and pathologists alike, of the germ-origin of many diseases. To settle this question satisfactorily experiments on living bodies must be carefully conducted. Such inquiries as these obviously present great, though perhaps not insuperable, difficulties, and they are certainly of the greatest importance. Apart, however, from this question of disease-germs, the conditions of pathological research at large do not lend themselves as yet to strict experimental methods.

Reviewing, then, the sciences which go to make up the knowledge on which the medical art is based, we cannot but acknowledge that the part played by pure experiment, and the results to be hoped therefrom, seem to be in decreasing ratio according to the increasing complexity of the material which we have to study, and that in consequence observation, suggested and guided by hypothesis, comes more prominently forward as the method by which we must at present endeavour to advance. For not only would direct experiment here in any circumstances be ever to a great extent precluded by the very conditions of the human subject-matter, but our knowledge of the natural processes involved is not sufficiently great for us to expect the best or any light from altering the natural conditions, or from *bonâ fide* experiment; and still less to justify our immediate search for an "experimentum crucis." For experiments in this field, indeed, we must greatly depend on those made by Nature herself in the shape of disease.

But though it may thus appear that medical knowledge, taken as a whole, is far from being exact, and only to some extent demonstrable by experiment and permissive of prediction, it by no means follows that its methods are un-scientific, or to be regarded as worthless and unfruitful because they are neither final nor fully satisfactory. It is unfortunately the case that in the very sphere of knowledge which most nearly concerns us all, the attainment to certainty seems hardest and farthest off. And perhaps from an unwillingness to acknowledge this unwelcome truth, many are found in the present day to be following scientific Will-o'-the-wisps, and dazzled by the newest lights, proclaiming loudly that experiment pure and simple is the only path of advance; observation alone taking us round in a perpetual circle. Such an opinion as this is the outcome of an imperfect appreciation of

the fact that a true method must be adapted to its material, and of an insufficient and erroneous notion of the function and possibilities of rational observation; and it is forgotten by those who thus contend, that the spirit which informs scientific observation and experiment is one and the same. There is, then, an important function for observation in the advancement of the scientific knowledge of disease; a function, too, which has already been so productively discharged in the past. The knowledge of our material is not sufficiently great to justify the conclusion that this method is useless or outworn, or that the time has arrived when, even from the scientific point of view alone, we may regard medicine in a purely experimental light. With no disparagement, therefore, it need scarcely be said, to the value of experiment properly devised and employed, with adequate knowledge of the conditions to be elucidated, we may advantageously glance at the results on medicine of observation in the recent past, and the hopes we may entertain from it for the future. It is but comparatively lately that the enlightened observation of men whom we delight to honour has put us in possession of invaluable knowledge concerning many diseases which before lay buried among a mass of confused symptoms. Many of the famous observers of modern days, ably following the method of Hippocrates, have illustrated in their own persons the saying of their great forerunner, that "he is the best Physician who can make the best Prognosis." A correct prognosis is at once the result of a knowledge of the natural history of disease, and indispensable to any rational line of treatment. To the careful observers of the school of medicine at Guy's Hospital alone, our debt is very large. To Bright, and Addison, and Hodgkin, we owe definite knowledge of maladies, without which much of our practice now would be indeed chaotic, and the work of several of their happily still surviving successors has been of great moment, as a perusal of the Hospital Reports will amply show. From the careful and unprejudiced observations of such men as Gull and Wilks, as well as of others in various quarters, much light has been thrown on different forms of paralysis both of cerebral and spinal origin, and on the previously little known manifestations of visceral syphilis. In our own day, too, clinical and pathological observation has almost revolutionized the study and treatment of fevers, the greatest triumph being, perhaps, the individualization in nosology of Enteric Fever, with our consequently improved power of fore-casting the result of this disease, and of both partially arresting its spread and favourably guiding its course. Nor in this rapid glance at the conquests of observation in medicine must we omit to notice the newer researches of the French and German schools, and the flood of light thrown on many nervous diseases by the work of such men as Erb, Charcot, and others. Before our eyes the various subdivisions of the spinal cord seem to be assuming a fresh clinical importance and interest from an able study of symptoms and post-mortem appearances by a host of modern observers, and we can scarcely guess at present how much will be gained for prognosis and treatment when further work and thought shall clear up the causation of the affections of this class which have so recently been made known to us. And if any further illustration be necessary of the value and acknowledged necessity of increased observation for the advancement of medicine, we may refer lastly, though not as least in importance, to the hopeful work of the Collective Investigation Committee of the British Medical Association, inaugurated as it has been by so many leading men, and so largely taken up. Not only in the investigation of little known diseases, but also in that of those long since acknowledged and described, is the want felt of more accurate and carefully ordered observation to make the knowledge of some the useful property of all; and it is indeed to affections of this latter class that the attention of contributors to this laborious undertaking is specially and with wisdom directed. It is well to remember, that not only is new study needed in all forms of disease for the advancement of medical knowledge, but also individual observation of what is already known is absolutely required of all those who would practise their profession aright. The work of others, however final and light-giving it may be, must be appropriated and felt to be our own before we can use it with confidence, and for the full benefit of our patients. There is probably much danger in the present day of forgetting this all-important fact in the confessedly laudable effort to extend the area of our knowledge, and to multiply discoveries by original research, especially when it is so easy to make a kind of scientific reputation by the invention, or even the use, of some new instrument of precision, or by the suggestion of a novel method of treatment. In clinical medicine especially, a thorough and personal grasp of what is already known is necessary for the productive prosecution of new inquiries.

It is perhaps in the domain of treatment that the inaccurate and unfounded antagonism we have alluded to between the methods of observation and experiment is most likely to be brought forward with some plausible appearance; and in a recent controversy, regarding the tentative use of a new drug, we have had occasion to point out this fallacy as occurring in some of the arguments adduced. Were our pathology far more advanced towards completeness than it is at present, and were there an equally increasing probability of curing diseases of the human body by extraneous medicaments, there might indeed be a wider justification than there is at present for trying the effects of drugs in a strictly experimental sense. But modern study appears to point in a different direction, and proportionately narrows this field of experimentation, not to mention the other limits assigned to it by conditions other than those which are purely scientific or medical. With these limits, and, indeed, with this special department of our subject, we have already, perhaps, sufficiently dealt in previous articles, but we refer to it here once more in order to emphasize the fact that in the sphere of therapeutics pre-eminently a careful study of diseases is absolutely necessary. This may seem a useless injunction and self-evident enough, but it is nevertheless too often disregarded. Owing, perhaps, to a natural longing to advance the healing art, or to add to our armamentarium, owing also to the great facility there is for constantly putting forward some new remedy owing to the frequent impossibility

of disproving allegations as to its efficacy, it is not rare to see a superficial regard of symptoms taking the place of scientific diagnosis based on observation ; and an entirely false assumption of the nature of a case being made, a claim to original research under the guise of the method of experiment is put forward in the sphere of tentative treatment. In proportion as the study of the nature of diseases is hurried and incomplete, so is this claim inappropriate and ill-grounded. Of all *specialties*, that of therapeutics being baseless is most misleading. Scientific treatment must ever go hand-in-hand with careful diagnosis : in this union there is strength ; but when therapeutical questions mainly engross the mind there is the ever present danger of relaxing our efforts in the search for causes, and proceeding at once, and at all hazards, to attack a symptom, often regardless of probably concomitant and undesirable effects. It is then an obviously superficial and unintelligent view, though not unrepresented in medical literature, that regards experimental therapeutics as the sign and seal of scientific advance in medicine, and that seeks, therefore, to discredit the method of observation by wrongly describing and depreciating it as old-fashioned and demonstrably fruitless. The truth rather is, that there is no real opposition between observation and experiment as methods of scientific research ; both are necessary in different proportions at different periods of advancement. An observation intelligently carried out is often tantamount to an experiment, and but few experiments conducted without knowlege founded on observation are of any value whatever, being indeed often fallacious, and, in medicine, dangerous. If we are to make advance in the study of the great and interesting subject of functional nervous disease, and to become better acquainted with the intricate matter of the physiology and the pathology of mind, it is clear that we must largely trust to the method of observation. In this vast field, experimentation, even if the soil were ready for it, would be necessarily almost entirely precluded, though much light on it may be looked for from the experimental method in comparative physiology and pathology ; and this leads us in conclusion to remark, that in the very same law which forbids us experimenting on our fellow-beings to their hurt for the sake of useful knowledge, we find a full justification of the proper use of the lower animals for this purpose. The practical test of our social and moral laws is the good of men ; their freedom, mental satisfaction, and bodily welfare. And if it be for this object only that it is allowable and necessary to use and sometimes inflict pain on the lower animals, it follows that our fellow-creatures, unless their civil status or their lives be forfeited, must ever remain exempt from penalties alleged to be for the good of the race ; for the good of men must always mean to our finite intellects the good of our individual fellow-beings.

A CHRISTMAS entertainment was given to the patients in St. Mary's Hospital on Wednesday last. The large ward in the new wing, which has just been completed was utilized for this very laudable purpose.

DR. COUVIDON'S REPORT TO THE FRENCH GOVERNMENT ON THE CHOLERA IN EGYPT.

THERE is reason to believe that within the next week Surgeon-General Hunter's complete report on the Cholera in Egypt will be given to the world. Its publication should be almost coincident with the initiation of sanitary reforms throughout the Delta, for it is generally understood that the British Government will be prepared to act upon the information their delegate has now placed in their hands. A review, therefore, of what Dr. Couvidon has to say upon the subject should have a special interest and value at the present time, for though his personal observations appear to have been chiefly confined to a small area of country, namely, Port Said and its neighbourhood, the conclusions he has arrived at are definite, and drawn in part from evidence collected throughout the whole country. Moreover, as the main question of interest, hygienic and commercial, is connected with the origin of the disease, anyone who is prepared to speak positively, and at the same time lay before his audience the grounds upon which his assertions are made, deserves to be listened to with attention. Through the courtesy of Surgeon-General Hunter we have been able to obtain a copy of the report Dr. Couvidon has issued.

The International Sanitary Conference, held at Vienna in July, 1874, is perhaps responsible for the popular belief that Asiatic cholera is always freshly imported from India; yet the Conference itself did not actually arrive at that conclusion. It agreed that "Asiatic cholera, susceptible of spreading (epidemically), was spontaneously developed in India, and that when it broke out in other countries, it had always been introduced from abroad, and that it was not endemic in any other country but India." This decision, however, does not say that when the disease has once been introduced, it may not exist permanently ; but the language in which the clause has been drawn up is sufficiently diplomatic to be misleading and therefore dangerous — misleading in the sense of allowing a loophole for misinterpretation, and dangerous in influencing those who concentrate the disease by enforcing quarantine and cordons. Since the Conference in 1874, many have raised their voice against the importation theory, notably Surgeon-Major Lewis in his official report upon the cholera outbreak at Aden in 1881. Now, Dr. Couvidon does the same thing, though evidently with the feeling that his cry will be in vain.

The cholera is stated to have first appeared at Damietta, on the 22nd of June ; and two Commissions, one delegated by the Conseil de Santé et d' Hygiène Publique, the other by the Conseil Sanitaire Maritime et Quarantinaine, met at that town on the 24th of June, to investigate the disease which had just made its appearance and to determine its nature.

The medical report of these two Commissions, though somewhat brief, is sufficiently conclusive ; the following are its last two paragraphs :—

"The Commission has endeavoured to find out whether those patients first affected by the disease belonged to the place itself, whether they had quitted it before falling ill, and whether they had had anything to do with persons or things coming from without."

"Being unable to collect any precise information on

these heads, and thus being without adequate data, the said Commission finds it impossible to establish the origin of the cholera epidemic which has appeared at Damietta."

"This statement is clear enough," says Dr. Couvidon, "but I am for my part even more precise : *I affirm, and I prove, that the present epidemic cannot have been imported.* During an epidemic, intemperate zeal exerted by officials may bring about formidable consequences affecting the public and commercial interests. It is not easy to determine the precise motives, either individual or general, which attribute the epidemic to importation, notwithstanding the statement laid down so clearly by the mixed Commission. But, however this may be, the fact remains that nameless Bombay merchants, and phantom ships full of merchandise, have been conjured up, and these are said to have brought the cholera from India to Damietta direct, without leaving any trace behind them at Suez and Zagazig. This is a hoax which has fortunately received no serious attention, either from the public or from official circles." Dr. Couvidon then deals with the old worn-out story of Mohammed Kalifa, the stoker on board the *Timor*, which has long been decided to be "yarn," and need not now be repeated. He concludes his remarks on the question of importation by showing how the littoral of Egypt has only two points at which ships coming from India can touch—Suez and Port Said—and how at neither of these ports was there any appearance of cholera, except among *such people as had come from Damietta.* "*Thus,*" he says, "*it is clearly proved that the present epidemic originated in Egypt.*"

Having in this way summarily disposed of the first question, he proceeds to the second—namely, the nature of the disease itself, and in this part of the report we come upon several interesting pathological observations, though the conclusions drawn from them are, perhaps, somewhat rash and premature. Three patients who came under his notice at Port Said had just arrived from Damietta, and presented all the characteristic symptoms of Asiatic cholera, but, in addition, the conjunctivæ were highly injected and there was delirium ending in coma. All three recovered, but upon a fourth and similar case, which ended fatally, an autopsy was made. Here the cavities of the heart were found distended with liquid blood, the meninges, brain and cerebellum congested, and the ventricles full of serous fluid. This condition Dr. Couvidon declares to be unknown in ordinary Asiatic cholera. He says : "Je n'avais observé rien de pareil de Cholera Asiatique ni en 1849 ni en 1853 ni en 1866 ;" and adds that the disease at Damietta was one *sui generis*, which might be called Cholera of Damietta, or Egyptian Cholera, until some more appropriate name could be found for it. Later on in the report he gives his own interpretation of the disease, and this is prefaced by information which is most interesting and not a little startling.

It appears that in 1868 there was a serious outbreak throughout the Delta, and especially at Damietta of the cattle disease known as "Epizootic." At that time the Viceroy, Ismail Pacha, required some animal charcoal for his sugar factories, so the governor of Damietta issued an order requiring the fellaheen to leave their cattle, when they died, in the open fields, so that the jackals, stray dogs, crows and insects might reduce their carcases to skeletons. Thus he hoped to obtain the bones required for the factories without expense. The order was carried into effect ; but notwithstanding the united efforts of crows, jackals, stray dogs, &c., the bones appear neither to have been picked clean nor removed to the factories.

It was during this time that Dr. Couvidon first noticed the outbreak of special troubles among the people, best described, perhaps, in his own terms "affections cutanées fort graves: anthrax, pustule maligne, ecthyma et enfin charbon pestiiential accompagné de bubons inguineux ou axillaires souvent suivi de fievre, de delire, de coma, et enfin de mort. C'etait bien réellement la peste a different degrés mais elle ne revetait pas un caractère epidemique et nulles mesures ne furent prises contre elle. Tels furent les résultats de la putrefaction â l'air libre de cadavres d'animaux."

After this Dr. Couvidon states that post-mortem examination of his patients disclosed cerebral pathological conditions analogous to those mentioned in the cholera cases already alluded to : and he adds that in Europe he has often met with symptoms resembling those of Asiatic cholera among people who have taken fluid charged with decaying animal matter. The most notable instance being that of a dissecting-room porter, who for a wager drank water from a bucket in which human remains were left soaking.

We now come to the conclusion Dr. Couvidon has thought fit to form upon the observations he has made : it amounts to a belief in the Egyptian form of cholera being a mixed type of the disease, or as he says "en grande partie du Cholera Indien, et en moindre partie de la Peste."

The different effect produced upon the people by the epizootic of 1868 and that of the late year is accounted for by the fact that during the former epidemic the carcases of the animals were scattered over a larger extent of land : thus the emanations from them were inhaled by the fellaheen in small doses only, while the products of decomposition were never drunk. But during the last epidemic of epizootic an astounding order was issued, the results of which, Dr. Couvidon says, are "as manifest and historical as those of the policy of Arabi and Company." It was to this effect—that every fellah who lost a beast from the disease should pay twenty piastres (about five francs) for the right to bury his animal. The outcome of this monstrous order, given to a people already over-taxed and broken, is easily foreseen : rather than attempt to pay a sum which many did not even possess, they cast their dead beasts into the rivers and canals, thus polluting the sole source of their drinking-water supply. Here, then, was an additional factor of disease added to an already sufficiently long catalogue, enumerated by Dr. Couvidon as follows :—General misery, traditional filth, want of air and light, narrowness of streets, encumbered with every kind of rubbish ; improper food, moral depression, want of courage, and terror. This disposes of the third question, namely, the causes of the disease. "Qui ne sont que trop facile à determiner et l'on doit être surpris que n'existe pas a l'epidémique permanent."

CLINICAL PAPERS.

No. III.—The Diagnosis of Mitral Constriction.

Simple mitral constriction is of far more frequent occurrence than is generally allowed, and its diagnosis probably presents greater difficulties than any other serious lesion of the valves on the left side of the heart. We exclude from consideration cases which are complicated by regurgitation, because the latter, when advanced enough to produce grave symptoms, is easily detected; and the presence of constriction as well in such cases is not of great practical importance. But when, as not rarely occurs, the question is whether stenosis of the mitral orifice be present, and the cause of serious symptoms, or whether the heart be healthy, and the distress and danger due to other conditions, accurate diagnosis becomes a matter of the utmost moment. In a typical case the observer feels a thrill at the apex preceding the impulse of the heart; he hears at the base a clear second sound over the aortic valves, an exaggerated one to the left of the sternum, and at the apex a rolling præsystolic murmur, gradually increasing in intensity and leading up to a short and sharp first sound, which is not succeeded by any appreciable second sound. The diagnosis of mitral stenosis under such circumstances admits of little doubt.

But in a second series of cases both murmur and thrill may be absent, and the heart's action regular, and the difficulty of detecting the disease then becomes great. The most striking auscultatory phenomena are accentuation of the second sound at the base to the left of the sternum, and, what is of much greater importance, a peculiar hesitation in the production of the first sound, a kind of hanging-fire, which is easier for the experienced auscultator to appreciate than to describe. Whatever be its origin, whether it be a faint sound caused by the blood passing through the constricted orifice into the ventricle, and so practically a murmur, or be due to a slowly beginning, though suddenly ending, ventricular contraction, it is a phenomenon which at once strikes the ear and suggests the nature of the disease. In these and all other cases of suspected constriction of the mitral orifice, the detection, if possible, of increase in size of the left auricle and right side of the heart, yields valuable corroborative evidence.

There is a third class of cases, in which there may be no murmur, no thrill, no hesitating first sound, but extreme irregularity of cardiac action, the beats being very frequent and very irregular both in rhythm and in force; so much so that a great many of them produce no pulsation at the wrist. In some cases as many as half the beats of the heart are not felt in the radial artery, so that the pulse there may be moderate in frequency, although the cardiac contractions succeed each other with extreme rapidity. Similar phenomena may likewise be observed in cases of simple dilatation of the heart with degeneration of its walls, such as occurs, for example, in chronic bronchitis and emphysema; but then the patient is usually past middle life. If grave cardiac symptoms be found in a comparatively young person, and if auscultation only reveal extreme irregularity in the heart's action, the presence of mitral stenosis ought to be at once suspected. The administration of digitalis in such cases not only often removes the patient's distress, and produces regularity and normal frequency of the heart's beats, but also facilitates diagnosis. For when the heart's action gets slow and regular a præsystolic murmur frequently makes its appearance.

Finally, there are cases of considerable mitral constriction which produce no sufficiently well-marked morbid phenomena to enable the observer to detect the presence of heart disease. But the pathologist not infrequently meets with these narrowed orifices in the post-mortem room in patients who have died from other diseases. The reflection is then forced upon him, how extreme some pathological conditions require to be before they come within range of our present powers of diagnosis.

Ω

REVIEWS AND NOTICES OF BOOKS.

THE CLINICAL WRITINGS OF DUCHENNE.[1]

There are few medical authors of modern times more universally known, or more deservedly appreciated, than Duchenne de Boulogne. This distinguished neurologist, by his indefatigable industry, by the brilliancy of his discoveries, and by his scientific and at the same time graphically vivid descriptive powers, ranks amongst those classical investigators whose labours will leave an indelible impression on the history of medicine. Like Celsus and Sydenham of former days, and Watson and Trousseau of more recent times, he was one of those great clinical teachers who not only during his life added a romantic charm to the study of medicine, but who by the value of his researches, the accuracy of his observations, and the soundness of his doctrines, has left to posterity such a rich store of knowledge and instruction as falls to the lot of few to have accumulated. Duchenne was an almost unique exception to the general rule, an example of an investigator of the foremost rank, who not only held no official position in his profession, but who did not even belong to the staff of any public institution. He himself tells us that, in order to carry out his own system of inquiry, he purposely declined to attach himself as physician to any hospital, as he believed that by so doing his range of observation would become a restricted one; but by utilising the property of others, which was always cheerfully placed at his disposal, there were no limits to his field of inqury. A further peculiarity in the character of this illustrious savant

[1] Selections from the Clinical Works of Dr. Duchenne (de Boulogne). Translated, edited, and condensed by G. V. Poore, M.D. The New Sydenham Society, London, 1883.

was the fact that he rarely studied the writings or investigations of his contemporaries until he himself had mastered the details of that particular research which he undertook; so that, as he expresses it, he might view the subject entirely from an independent aspect, and not through the spectacles of another. From this point of view, most of his work may be said to have been original; although it is well known, and he himself admits, that in many instances some of his discoveries have been shared, or even anticipated by others. There are, however, few branches of medical science to which his attention was directed which he has not adorned with a masterly hand, and there are many which to him entirely owe their existence. Besides a mass of contributions to the literature of his time on a variety of subjects, his two great productions of "L'Electrisation Localisée," and "Physiologie des Mouvements" alone constitute an era in the history of medicine, and will remain as standard works of reference while that science continues to exist.

The labours of Duchenne are already so well known and universally recognised in this country, that a translation of his works seems to have been superfluous. We have, however, before us a volume produced by Dr. G. V. Poore, under the auspices of the New Sydenham Society, the addition of which to an English Standard Library cannot but be looked upon as a national compliment to an illustrious confrère, even if its contents are not novel to the educated physician. Duchenne was a most prolific and voluminous writer; and his somewhat diffuse style, added to the enormous extent of his researches and observations, have led to the accumulation of a vast hoard of literary material. The arrangement of the work under notice has been carried out with judgment; and in a concise yet comprehensive form, all the characteristic and important conclusions of the author are presented to the English reader. The editor points out that, as the electrical investigations of Duchenne have already been translated by Dr. Tibbits, he has confined himself to a reproduction of those researches on clinical medicine with which the name of the author has been more especially associated, and which have been selected from his various writings. These have been in certain parts abridged, yet the essential features have been maintained.

To attempt a criticism of the works of Duchenne would be here not only out of place, but, on account of the vast field over which they extend and the important issues they comprise, by the ordinary reviewer would be impossible, if not disrespectful to the memory of the departed genius. They are the efforts of a great master, and their doctrines must stand on their own merits, to be judged of by posterity in the light of the future advances of science. A re-perusal of the works of this author on many of the diseases which he studied and described, indicates how little has really been added to our knowledge of these affections since his day, in spite of the improved modern methods of research now at our disposal, and how admirable was his graphic delineation of their salient features. His narrative, descriptive of Locomotor ataxy, for example, remains almost perfect, according to our present knowledge of the disease, and with the exception of a few minor points of detail his representation still remains unsurpassed. If the discovery of this malady was not entirely due to Duchenne, as he believed it to be, there can be no doubt that to him is owing not only its name, but the first clear and definite portrayal of the associated symptoms in that form, which has established to the world the clinical and pathological picture of the disorder. How ample also and how accurate is his description of what has now received the modernised terminology of acute and chronic poliomyelitis! Here again, with the exception of one or two minor points, no practical additions to our knowledge of the disease have been made since his day, and in all essential features his description may still be ranked as the standard representation of these morbid states. Of Pseudo-hypertrophic spinal paralysis, the name he gave to what is also known as "Duchenne's paralysis," his account may even now be looked upon as more or less complete. In this affection the author does not seem to have observed its occurrence in adults, believing it to be exclusively a disease of infancy or childhood. We now know however that, although somewhat rare, it not unfrequently appears later in life, and many characteristic cases have of late years been published in evidence of this. Duchenne also does not appear to have attributed any importance to the atrophy of muscles which forms so important a complication to this pseudo-hypertrophy. With these exceptions little has been added to our knowledge since the original monograph on the disease by its discoverer. Almost the same can be said of many of the other conditions which Duchenne delineated, a fact which gives further evidence of the marvellous industry, perseverance, and penetration of that cultivated physician.

At the same time science is always advancing, new lights are thrown on its phenomena, additional facilities are obtained for inquiry, and fresh revelations are disclosed. Even since the time of our author, progress in the histology and pathology of the nervous system has made vast strides, and many of the doctrines only predicted by Duchenne, and put forward by him as hypotheses from analogy, are now demonstrated to have actual existence in fact. Twenty years ago the microscopical conditions of the morbid nervous centres were practically unknown, and their appreciation was attended with great uncertainty and doubt. Now many of these have been determined with the utmost precision, their characteristic features displayed, and their association with certain clinical states clearly recognised. The art of physical diagnosis, which is so important in the investigation of all diseases, and which is more particularly wanting in those of the nervous system, has made improved steps in advance. The discovery for example of the tendon phenomena has given a great impulse to diagnosis and greatly facilitated our conceptions of many morbid states. The advantages of this method of inquiry were unknown to Duchenne, and its general adoption by neurologists is only of very recent date. The science of electro-diagnosis has also by its extended improvement added further assistance to our appreciation of disease. Although Duchenne was the great pioneer and champion of electrical investigations, he almost entirely limited his attention to the effects of the induced current. More recently however, mainly owing to the exertions of Remak, Ziemssen, and Erb, galvanism has in addition been utilised in the same direction. However important may be the revelations of one of these agents alone, there can be no doubt that the employment of both together has been a real advance in the art of diagnosis. Duchenne overlooked the value of the continuous current for this purpose; but later investigations have proved that this, in conjunction with faradaism, is a more powerful auxiliary in the hands of the physician than when the last only is employed. Thus medicine is essentially a progressive science, and the labours of one generation, although they are the necessary pioneers to those of the succeeding one, are rarely found to hold their own with the subsequent discoveries of those which follow. This cannot as yet be said of the works of Duchenne, which now, and in all time, will continue to rank, like those of some of his great predecessors, as lasting monuments of his industry and genius.

CLOUSTON'S CLINICAL LECTURES ON INSANITY.[1]

By giving his book the title of "Clinical Lectures," and by keeping pretty steadily to the intention that this title expresses, Dr. Clouston has been able to evade the greatest difficulties that cluster round the subject of insanity, and to produce a work which raises no abstruse psychological questions, stirs none of the deep problems that concern the connection of mind with matter, starts no dazzling theories, but deals with the concrete practical matters which the asylum physician has daily and hourly to examine and decide, and with which every medical practitioner must more or less often come into contact. The aim of a book which deals with insanity from a clinical point of view only is not a very ambitious aim, but it is an eminently useful and serviceable one, and it has the enormous advantage that it is attainable; an advantage that does not appear yet to belong to the systematic treatment of the subject. The wisdom of Dr. Clouston's determination to limit himself to the concrete aspects of his subject is shown by the result. He has succeeded admirably. As a guide to the management and treatment of insane people, and to the best known means of curing their malady, the book is excellent. It is the epitome of many years' experience of an acute, patient, shrewd observer, and of a sagacious physician. The author keeps his clinical practical aim steadily in view. He rarely loses touch of his facts. He rarely makes a statement of fact without bringing up evidence in support. His pictures of clinical cases, of which he gives some 260, are graphic, concise, and true; and scattered through the book are many acute reflections, and some that are even profound.

Dr. Clouston has, however, the defects of his qualities. In clinical lectures for the use of students and for the guidance of medical practitioners, insanity must of course be looked on as a disease, or (on Dr. Clouston's method) as a group of diseases. Against this there is not a word to be said. But the author is not content with this. He endeavours in every possible way to assimilate insanity to bodily disease, to view the one as a variety of the other, and to apply to the former the terminology of the latter. The inevitable result of such endeavour is confusion. There is, indeed, a superficial and very misleading appearance of simplicity in the use of such phrases as "paralysis of appetite," "paralysis of self-love," "paralysis of thinking and volition," "anæsthesia of conscience," "mental protoplasm," and other expressions in which psychological facts are spoken of in terms that are properly applicable only to physiological facts; but the apparent simplification is dearly paid for by the confusion that is produced between two distinct classes of facts. Dr. Clouston's classification is an extremely good one for the purpose in view—the clinical distinction of varieties of mental disorder—but it is vitiated by the mongrel terms that he applies to his groups—Psychalgia, psychlampsia, psychokinesia, psychocoma, psychoneurosis, and psychoparesis. Psychalgia he speaks of as mental pain, as if there were some other pain which is not mental. The other terms bring into forced contact two ideas that refuse to amalgamate. Eclampsia is a sudden and excessive muscular contraction, caused by a sudden and excessive nervous energising, and applied to bodily processes it has a clear meaning; but when this term is applied to mental processes, it ceases to have a meaning, for mind has no muscles to contract and no nerve centres to energise. Coma we know as a bodily condition, accompanied by loss of consciousness. Psychocoma should be then a mental condition, accompanied by loss of consciousness, which is a contradiction in terms; and similarly with the other names.

Dr. Clouston keeps as far as possible aloof from all reference to the subjective aspect of mind—its composition, divisions, and faculties—but he is sometimes compelled to deal with it, and then is not very successful. In a systematic treatise on insanity this would be a serious defect; in clinical lectures it is not perhaps of much moment, but still a lecturer on mental disorders should not make such a statement as that "The chief faculties, looked at from the mental point of view, are consciousness, perception, ideation, and judgment, volition and mental inhibition, affective faculty or all that relates to feeling and emotion, memory, power of attention, representation and imagination, association of ideas and speech" (p. 24). Nor should he speak (p. 450) of "an identical and simultaneous lesion affecting both the motor and mental ganglia." These blemishes are found, however, only where Dr. Clouston is compelled to touch upon the difficult aspect of the subject, which is scarcely brought into view in clinical work, and they do not in the least affect the accuracy of his portraiture of disease or the excellence of his therapeutic teaching. But as they arise from that neglect of the study of normal psychology, which is so general among those who have to treat disorders of the mind, it is right to point out that even the most practical and experienced psychiatric physician cannot afford to dispense with this branch of knowledge. Like all practical men, Dr. Clouston theorises occasionally, and, as is usual in such cases, he is apt to present his theories in the guise of facts. "There is no doubt," he says (p. 381), "that apoplexies and all sorts of other gross limited lesions produce, in unstable brains, great convolutional disturbance *through reflex excitation*" The words we have italicised convey a theory which is new and requires further explanation to become intelligible.

The literary style is, like the thoughts, as a rule vigorous and lucid. On the whole, it is exceptionally clear and intelligible for a book on insanity; but here and there we meet with terms and phrases that fail to convey a definite thought—such as "mentalisation," "religionism," "the law of solidarity of action" of the brain; and occasionally we find a slip, as on p. 371, where a patient is said to "smell pepper." But these defects are few and rare, while the merits of the book are conspicuous on every page. As to the clinical teaching which forms the bulk of the work, little need be said. If he had not previously done so, Dr. Clouston has by this book established his reputation as one of the very first authorities of the day in his specialty, and he worthily maintains the traditions of the British school of psychiatry.

[1] "Clinical Lectures on Mental Diseases," by J. S. Clouston, M.D., F.R.C.P.E. J. & A. Churchill, 1883. Crown 8vo, pp. 631. Illustrated.

Hurry, Worry, and Money: the Bane of Modern Education; by T. PRIDGIN TEALE, M.A., Oxon, F.R.C.S. Leeds: Goodall.—This is the address recently delivered by Mr. Teale at the recent Social Science Congress, supplemented by an appendix containing a mass of evidence and opinion in support of the views advanced in the address. The whole forms a most powerful indictment against the modern system of education, and deserves the earnest study of every doctor, of every parent, and of every politician. The vast majority of the members of the medical profession, who have exceptional opportunities of forming an opinion on the subject, will agree with Mr. Teale, that education in England is drifting away from a high, wholesome, and sound standard, that the increasing tyranny of innumerable examinations is spoiling the work, and wasting the energy of industrious men and original thinkers, sacrificing the industrious in order to whip on the idle and indifferent, and forcing the accumulation of information at the expense of training. The question is essentially a medical one; education to be really safe and successful must, as Dr. Crichton Browne has contended, be conducted "in harmony with the laws which medical science teaches." We should like to see Mr. Teale applying his principles in another pamphlet to the modern system of medical education, a subject on which he could speak with, if possible, even more authority than on the subject of education in general.

Medical Diagnosis. A Manual of Clinical Methods; by J. GRAHAM BROWN, M.D. Second Edition. Edinburgh: Bell and Bradfute, 1883.—The favourable opinion which we formed of this work a few months ago is fully confirmed by the speedy appearance of a second edition. The value of the book has been very considerably increased by the insertion of copies of the plates of Ziemssen's motor points; the sections on the use of the ophthalmoscope and laryngoscope also constitute useful additions, and we wonder that it did not occur to Dr. Brown to give some general directions for ascertaining the causes of deafness; surely it is not necessary to relegate a patient to a specialist to decide whether he is suffering from Eustachian or tympanic deafness. We hope that in the next edition this little want will be remedied; and we would suggest also, in reference to future editions, that locomotor ataxy is not usually regarded as the most common cause of nystagmus, and is, indeed, so rarely, if ever, a cause of it, that any mention of it might have been safely left out.

Anæmia; by S. LAACHE, Christiania, 1883, pp. 276.—This work, undertaken by Dr. Laache at the instigation of Professor Worm Müller, presents the results of a long series of observations made by its author in the Physiological Institute of Christiania, upon the various forms of anæmia. The experiments ranged over a fairly large field of material, and were directed especially towards the determination of the relative alteration in number and size of blood corpuscles and their variation in hæmoglobin-contents in a series of the so-called "blood-diseases." As a basis from which to work, an analysis was made of observations upon sixty cases of persons in presumably perfect health. From this it appeared that the average number of blood corpuscles per cubic millimetre was, in men, 4·97 million, and in women, 4·43 million. The hæmoglobin ratio per cubic millimetre was, in men, 0·112 milligrammes, in women, 0·099 milligrammes. Observations were then made upon cases of anæmia after hæmorrhage in healthy and unhealthy subjects respectively. In the former cases the results proved that the number of red corpuscles may fall far below 50 per cent. of the normal quantity without a fatal issue. The mode of regeneration of red corpuscles was studied at the same time, and Dr. Laache observes the excessive number of microcytes present in the specimens of blood taken during the period of recovery after hæmorrhage and notes the small amount of hæmoglobin which the new corpuscles at first appear to contain. In one case of recovery after severe purpura hæmorrhagica, however, the regeneration of the corpuscles and of their hæmoglobin-contents appeared to go on simultaneously. The anæmic conditions supervening upon typhoid fever, Bright's disease, phthisis, &c., were each in turn examined. The investigations into cases of chlorosis are given very fully. The action of iron in aiding the reproduction of corpuscles is also carefully considered, and a confident opinion expressed that its influence is chiefly to be noted in the hæmoglobin-content of the cells rather than in the increase in the number of the cells themselves. The subject of "pernicious" anæmia is treated at greater length, and the observations upon the cases recorded form a valuable contribution to the literature of the disease. Eleven cases accurately observed and carefully reported, most of them rendered complete by post-mortem examination, form solid material from which to draw conclusions. The frequent occurrence of microcytes in this, as in other forms of anæmia, led Dr. Laache to investigate them with especial care, and he records his belief that they are in reality simply small sized red corpuscles. In reply to the observation made by other investigators, that they sometimes assume a globular form, he points out that this only occurs when the blood is diluted with a saline solution, and is not to be found in any preparation of undiluted fresh blood. The poikilocytosis observed by Quincke and others, is regarded by the author as by no means characteristic of this form of anæmia, and he suggests the possibility of artificial modifications of form as a result of preparation. His own observations lead him to regard the occurrence of large highly coloured blood discs as more truly pathognomonic of the disease. The work, which concludes with some useful observations upon leukæmia and pseudo-leukæmia and a series of illustrative charts, bears upon it the stamp of genuine study and careful observation. Whilst enunciating clearly his own deductions from the observations which he records, the author does not disregard the opinions of previous workers in the same field.

Diseases of the Brain and Spinal Cord: by DAVID DRUMMOND, M.A., M.D. *London: Henry Kimpton*, 1883.—The amount of attention that has been given of late years, and is still being given, to diseases of the nervous system, would probably cause considerable surprise to some of our predecessors, who managed to put all they wanted to say on this subject in as many lines as it now takes pages. The volume before us is addressed to students and practitioners. We think that it will prove of more service to the latter than the former, mainly because the various descriptions seem to us to assume, and certainly require for their due appreciation, a certain amount of knowledge on the part of the reader. In his preface the author apologises for the rough character of some of his illustrations on the score of expense; it is an excuse for, but not a justification of, a defect, to which we should certainly have otherwise called attention. In discussing the differential diagnosis of apoplexy due to cerebral hæmorrhage from that due to other causes, we would prefer to almost reverse the order in which he deals with these latter, and would say, that cerebral hæmorrhage is to be distinguished first from an epileptic fit, then from alcoholism, injury to the head, narcotic poisoning, and uræmia. To place uræmia first on the list is, to our thinking, misleading, as the student might thereby infer that this was the most common condition likely to be mistaken for cerebral hæmorrhage. It seems to us, too, that Dr. Drummond does not lay enough stress on the important aid to be derived from the history of the case. In the absence of a history, it is often impossible to exclude epilepsy or injury; and, on the other hand, it is sometimes possible to arrive at a correct diagnosis of cerebral hæmorrhage from the history alone; another point, too, which is sometimes of great value, but to which no reference is made, is the condition of the pupils—a patient in a state of coma with unequal pupils should never be treated as suffering from the effects of drink alone. The chapters on basilar meningitis, and meningitis of the convexity, are amongst the least satisfactory in the book. The symptoms of the latter affection are, indeed, most obscure, and it seems to us that Dr. Hammond is really describing cases of acute general meningitis, which are not very uncommon, and are often probably of a pyæmic nature. Such symptoms, for instance, as irregular respiration or retraction of the head, point to a basic affection

rather than one of the convexity. Nor can we agree with the statement, that in tubercular meningitis optic neuritis is seldom met with, and that in simple meningitis of the base it has been observed with tolerable frequency, our own experience pointing to an exactly opposite conclusion. The chapter on syphilis of the brain contains a concise account of the various lesions that may be met with—periostitis, caries, pachymeningitis, gummata of the pia mater, sclerosis, periarteritis, endarteritis, and neuritis. The extreme importance of the early recognition of the fact, that any given symptom is the result of a syphilitic lesion of the nerve centres, gives to this subject a value at least as great as that of any other in the whole range of diseases of the nervous system, and the precision with which the symptoms and diagnosis are given in this chapter proves that Dr. Drummond is fully alive to this fact. The insertion of a chapter on general paralysis of the insane is certainly a step to be highly commended. In these days of specialists, we are too apt to relegate this disease bodily to the alienists, and one result of this is that the majority of practitioners cannot recognise the disease when they meet with it, often to the very great detriment of their patient and his friends. The last part of the book is devoted to diseases of the spinal cord. Dr. Drummond is in accord with all modern writers as to the pathology of infantile paralysis, progressive muscular atrophy, and locomotor ataxy, but he differs from the majority of them in including pseudo-hypertophic paralysis amongst the diseases of the spinal cord. He apparently relies mainly on a case in which he had himself examined the spinal cord, and found that "disintegration of the lateral gray network, especially of the left side, and most marked in the lumbar enlargement, was clearly discernible; and in addition there was a conspicuous bulging on one part of the left lateral column, due to a cavity containing serum which was surrounded by gray matter, and extended a considerable distance up the cord from the lumbar enlargement. The ganglionic cells appeared to be normal." It appears that Dr. Bramwell and Dr. Gowers had previously described very similar changes, which, however, neither of them seems to have considered of much moment. It does not appear to us that there is as yet such evidence as would justify us in classifying the disease in question as a disease of the spinal cord. Although neither chorea, tetanus, hydrophobia, paralysis agitans, nor any of the many forms of neuralgia or spasmodic affections find a place in this book, it is nevertheless a work which, as we said at the commencement of our remarks, will be of much service to the busy practitioner.

Sir Thomas Browne's Religio Medici; a Facsimile of the First Edition. Eliot Stock, 1883.—This delightful edition of a delightful classic should have the effect of making Sir Thomas Browne known to many of his modern successors who have never before studied him. It is admirably printed in old type, is bound in stamped oak boards, and is altogether a book to be treasured. The *Religio Medici* is chiefly of interest as conveying the picture of a rare and loveable mind, and as an example of a prose style of exquisite strength and delicacy. Like all great classics it exerts a powerful charm upon the reader and carries him in imagination out of this age of hurry back to a period which, but for its meditative calm, seems singularly akin to the present. Sir Thomas Browne had many qualities which should endear him to the medical reader. He was largely tolerant, happy in disposition, bold and independent in speculation, free from petty prejudice, fond and at the same time distrustful of paradox, and full of imagination, and of a quaint quiet humour. His mind was a strange mixture of the sceptical and the superstitious. Some of his views, which seemed startling to his contemporaries, are to-day accepted as commonplaces, while in other respects he cherished beliefs that are now universally discredited except at the Psychical Research Society. Nothing can better express the distance from us of the time in which he lived, and the nearness to us of himself, than the following passage:—"I feele not in me those sordid and unchristian desires of my profession, I doe not secretly implore and wish for Plagues, rejoyce at Famines, revolve Ephemerides and Almanackes in expectation of malignant effects, fatall conjunctions, and Ecclipses: I rejoyce not at unwholesome Springs, nor unseasonable Winters, my Prayer goes with the husbandman's; I desire everything in its proper season, that neither men nor the times be out of temper. Let me be sicke myselfe, if sometimes the malady of my patient be not a disease to me. I desire rather to cure his infirmities than my owne necessities. Where I doe him no good me thinkes it is no honest gaine, though I confess it to be the worthy salary of our well-intended endevours. I am not onely ashamed, but heartily sorry, that besides death, there are diseases incurable, yet not for mine owne sake, or that they be beyond my art, but for the general cause and sake of humanity, whose common cause I apprehend as mine owne." That is very finely said, and though it is almost the only passage in this book in which the author speaks of his own profession, it is a fair sample of the whole. The reader who would study Sir Thomas Browne will find an admirable essay on him in Mr. Leslie Stephens' "Hours in a Library."

The Diagnosis and Treatment of Diseases of the Ear; by OREN P. POMEROY, M.D. New York: Bermingham and Co.—A number of text-books on aural surgery have been published of late, so many, including new editions of old works, and translations of German authors, that we should hardly have thought another book on the subject needed. Dr. Pomeroy, however, seems to think otherwise, and we feel bound to admit that he has written a valuable and very readable work. In two respects Dr. Pomeroy departs from the plan generally adopted by writers on aural surgery. In the first place he has left out the introductory chapters on the anatomy and physiology of the ear. In the preface he very properly says: "Where it is desired to study the anatomy and physiology of the ear thoroughly, the books devoted to such subjects treat the matter more exhaustively than ordinary text-books on the diseases of the ear, can possibly do." Why authors should deem it necessary to turn to a work on anatomy, and extract from it more or less fully the chapters on the structure of the ear, has always been a mystery to us. They do not pretend that the material is original, and do not even attempt to stamp their individuality on the description, with the notable exception of Professor Politzer. To return, however, to Dr. Pomeroy's book; it is not disfigured in the second instance by cases spread *ad nauseam* throughout its pages. The cases given are aptly chosen, and more frequently than not are taken from the practice of others. The book is not a mere compilation. One feels the individuality of the author in almost every page. Each disease is treated of with due regard to its importance, or to what is definitely known about it. The description of acute purulent, and non-purulent catarrh of the tympanum, is as finely written as anything we remember to have read on the subject. In conclusion, we can heartily commend the book to the favourable notice of our readers, and we feel sure it will take its place among the best text-books on diseases of the ear.

The Dissector's Manual; by W. BRUCE-CLARKE, M.A., M.B., and C. BARRETT LOCKWOOD, F.R.C.S. *Cassell and Co., London*, 1883, pp. 390.—In this manual an attempt is made to collate the broad facts of anatomy, with a view to giving the student "a description of the way in which the structures that go to make up the human body may be displayed." Prior to entering upon a description of each dissection, the authors direct the student's attention to the position of the more important underlying structures, and excellent instructions are given for marking them out on the surface of the skin. Chapters three and four are sufficiently clear to be of service to the student who is learning to dissect; but the remaining portions of the book are compressed to such an extent, that, it seems to us, the student would be so confused with the mass of facts presented to his notice, that he would derive but little benefit from their perusal. This compression of the latter part of the work is the more to be regretted, as the major part of the first, and the whole of the second, chapter might well have been omitted. It is no doubt true, that the greatest ignorance often exists

among students as to the meaning of the simplest terms; but, surely, a glossary, in which such words as "*capsule*," "*dissect*," and "*clean*" are explained, is an unnecessary addition to the work. We must take particular exception to the chapter on the preparation of the body for dissection. There appears to be an increasing inclination on the part of authors of anatomical works to treat of *anatomical technics*, and, though in a large systematic work, a chapter on such a subject might be admissible, it is wholly out of place in a popular students' manual. The study of practical anatomy has hitherto been conducted without any undue publicity, and we think it is extremely injudicious to call unnecessary attention to the methods by which it is prosecuted, and to acquaint those external to the profession with the duties of a dissecting-room porter. (*Vide* pp. 14, 15.) We are aware that this is an era of manuals and aids, and pocket editions; still, we must confess that, though this little book contains many interesting and valuable hints, it is not at all clear to us what part in anatomical literature it is destined to occupy; and we would still prefer to see a student take his "Ellis" and patiently study his subject until he thoroughly understood it. The lett-r-press requires revision in many places, as such expressions as "a good foot," "if the foot is a really good one," and, again, when writing about the mammary gland, the statement that "a female about 30 years old would be the likeliest to afford a good one," might be altered with advantage.

The Alienist and Neurologist, Oct., 1883.—This quarterly journal maintains, on the whole, its high character, but its pages are disfigured by a bitter personal controversy concerning the case of Guiteau. A translation of Dr. Bianchi's article on Changes in Handwriting is of some interest. Dr. Kieman relates a third case of insanity from quinine, in which the causation appears indisputable. Dr. Van Derveer of New York, has removed Meckel's ganglion for the relief of severe facial neuralgia, with complete recovery from both the operation and the neuralgia in two cases, and partial relief in a third. The ganglion is exposed from the front by trephining the front and back walls of the antrum of Highmore. The editor contributes some useful hints on the minor treatment of insane patients, and the value of the number is enhanced by a fairly complete bibliography for the preceding twelve months. This section concludes with the declaration that "the hour is coming when it will be a proud distinction to a man that, living in the last quarter of this nineteenth century, he simply did his duty, neither speculated nor peculated; and, dying universally respected, they wrote above him as the best evidence of his philanthropy, this inscription: "For he had compassion on the multitude, and published nothing—not even his memoir."

The American Psychological Journal, Oct., 1883, continues its useful work of endeavouring to improve the position and treatment of the insane. The chief article in this number is a strenuous insistance on the point, often urged in these columns, that the business of asylum medical officers is not to manage the farm, or purchase the stores, or supervise the machinery, but to treat the patients. This desirable limitation of their duties is, however, as far off as ever, and there is not yet the slightest sign of its approach. Meanwhile, our knowledge of insanity is at a standstill, and our treatment is chiefly castor oil.

Elements of Practical Medicine; by A. H. Carter, M.D. Second Edition. London: H. K. Lewis, 1883.—As an introduction to medical students at the outset of their professional studies, this book is well adapted to its purpose, and the present edition seems to be as full of information as could reasonably be expected from its size. There are two doctrines, however, contained in it upon which the student will do well not to retain a firm hold; one is the view that the large white kidney ultimately becomes a typical granular kidney; the other, that membranous laryngitis "may probably, in some cases, be due to diphtheritic infection, and in others to severe inflammation of a non-specific kind." It is true that membranous laryngitis is not always due to diphtheria, but in the very large majority of cases it is so, and the quotation we have given is decidedly misleading.

ABSTRACTS AND EXTRACTS.

The Pathology of Cervical Erosions.—A recent number of the *Zeitschrift für Geburtshülfe und Gynäkologie* contains a long article by Dr. Carl Ruge, of Berlin, on the above subject. It is mainly devoted to the consideration and refutation of the views of Fischel[1] as to the origin of these erosions. The position of the question is this; according to Fischel, as our readers will be aware, cervical erosions are due to the stripping off of a superficial layer of pavement epithelium, and the consequent exposure of a glandular and papillary structure which previously existed underneath the last epithelial layer. This glandular structure he regards as a prolongation of the structure of the cervical canal beyond the external os, or, in other words, a physiological ectropion of the cervix. Ruge regards them as due to a new formation of glandular and connective tissue. He holds that no glands whatever exist beneath the epithelium of the healthy vaginal portion of the cervix. One of the main arguments advanced by Fischel is, that he has found glandular structure like that of the cervical canal, and the so-called granular erosion, on the vaginal portion around the os externum of newly-born infants, and also of virgins and nulliparous women. Ruge, in commenting upon this, says that the microscopical appearances of the granular erosion are perfectly distinct and different from those of the cervical canal. The morbid appearance of an eroded cervix often stops abruptly at the external os, the mucous membrane of the canal being healthy. The glands of the healthy cervix are more elongated, they show in their whole course little difference in breadth: while those of the erosions present numerous rounded bulgings-out, and collections of mucus; on section their borders appear like papillæ between which their orifices are irregularly disposed. Ruge has examined many specimens of the healthy cervix uteri, and has always failed to find glands on the vaginal portion; and in this he is supported by similar failure on the part of other independent observers. He therefore concludes that the glandular structures seen on the eroded cervix are not pre-existing glands, but new formations. Another argument which he advances, is the mode of healing these erosions, a process which he has watched step by step. The glands gradually diminish in size; their single layer of cylindrical epithelium changes into several layers of pavement epithelium, and the gland cavities become filled up. These changes sometimes take place uniformly over the whole surface of a gland: sometimes at one side of it only, and the appearance of a microscopic section varies accordingly. He therefore argues, that as they disappear in loco so they may arise in loco. The next piece of evidence which our author brings forward is derived from the examination of the hymen (or rather vaginal septum), in cases of hæmato-corpus. He found on the external surface of this membrane pavement epithelium, on the internal, cylindrical epithelium and glandular structures. He points out that there is a stage in the development of the genital canal in which the whole of it is lined with cylindrical epithelium; and thus the structure of the internal surface of the vaginal septum is only a persistence of a temporary natural condition. The bearing of this in the theory of Fischel is, that it shows that the presence of glands and cylindrical epithelium is not peculiar to the cervical canal, and that the existence of such structures on the vaginal portion of the cervix does not demonstrate that where they are found ectropion of the canal is present. Dr. Ruge has moreover examined cervical erosions in newly born children, and has found the histological appearances characteristic of them continued on to vagina. A further argument is derived from his own researches into the histology of cancer of the uterus. He holds that the appearances of cancer originating in the cervical canal, and the same disease commencing on the vaginal aspect of the cervix, are quite distinct: that he has traced the development of each form of the disease out of simple erosions; and that as the disease to which the two kinds of erosions lead is different, therefore the erosion of the vaginal portion is not a mere continuation of the cervical structure, but a new and different formation.

[1] *Medical Times and Gazette*, 1881, Vol. I., p. 107.

Histological controversies seem often of little moment in practice; but in this case the question at issue has important practical bearings, for we are told by Americans that almost all cervical erosions are nothing but the cervical mucous membrane, exposed by eversion, in consequence of laceration during childbirth, and are to be cured only by repairing the torn cervix. If Dr. Ruge be correct, that the common granular erosion results from a morbid process having its seat quite outside the cervical canal, it is clear that trachelorhaphy cannot be so often requisite as some of its advocates would have us believe.

Kairin in Acute Rheumatism.—A paper by Dr. H. Menche, of Rheydt, published in the *Centralblatt für Klinische Medicin*, No. 47, 1883, forms a small but instructive contribution to the slowly accumulating evidence of the action of kairin, the latest antipyretic drug. The experience of the writer as to its action in the pyrexial stages of pneumonia, pleurisy, and pernicious anæmia is by no means so satisfactory as that of some other observers. It cannot fail to be noticed, however, that a very large dose was employed in every case. In a case of asthenic pneumonia, in which one gramme of kairin was given every hour for seven hours, a marked reduction of temperature took place, but at the same time the toxic effects of the drug became very manifest. It should be added, that large doses of quinine and smaller doses of kairin had been tried previously without result. Depression of pulse, rigors, discolouration of urine, and a marked tendency to collapse were the symptoms accompanying the reduction of fever. In phthisis and anæmia similar effects were produced, severe sweating being also present in the former case. In a case of typhoid fever, in which hyperpyrexia had been uninfluenced by baths and quinine, the administration of seven and a half grains of kairin every hour for five hours had a very powerful effect in reducing temperature, but at the same time severe rigors, great depression of pulse, and delirium rendered the features of the case rather more serious than they had been before. Noting the points of resemblance between kairin and salicin, viz., their rapid antipyretic effect, and their tendency to induce delirium and other toxic symptoms, Dr. Menche tried it upon a case of acute rheumatism. The patient had been ill for six days, and several joints had been affected. Three and a half grains of kairin were given three times in one morning, and seven and a half grains four times in the same afternoon. Severe sweating was induced. Less pain was felt, but the joints were still tender in the evening. On the following day the drug was given again in smaller doses, with still further relief to pain. A relapse followed in twenty-four hours, pain returning as severely as before, with signs of pericarditis. With the free use of kairin (seven grammes in twelve hours) the pain and febrile disturbance were again reduced. The whole illness lasted nineteen days, during nine of which the patient took fifty grammes of kairin. A second case, of a patient with long-standing mitral disease, was also treated with frequent doses, with equally good results. Dr. Menche's experience of the drug thus leads him to compare it favourably with salicylate of soda as an antipyretic in cases of acute rheumatism, but to use it with caution in cases of other specific fevers.

Vaginal Cysts.—Dr. Max Graefe, of Berlin, contributes to a recent number of the *Zeitschrift für Geburtshülfe und Gynäkologie* a short but interesting paper on vaginal cysts. He believes that these are less uncommon than is generally supposed, because they generally cause no suffering, and therefore are probably often unnoticed. He gives an account of ten cases under his own observation (occurring in Prof. Schrœder's clinic), in each of which a careful microscopical examination of the cyst wall was made. Adding to these cases published by Winckel, Klebs, and other writers, our author arrives at the following conclusions:—Out of 61 cases, in 29 the cyst was on the anterior vaginal wall, in 21 on the posterior, and in 11 laterally situated. He points out that this statement must be taken with the qualification that in many cases the cyst is not seated exclusively upon either vaginal wall. The colour, consistence, and morphological elements of the cyst contents differ widely, even in cysts apparently similar in structure. The thickness of the cyst wall varies from a millimetre to a centimetre. It is composed of connective tissue, with, in thick-walled cysts, smooth muscular fibres, that is, the structure of the vagina. Outside it is covered with pavement epithelium, like that of the vagina. Internally most cysts are lined with cylindrical epithelium, but now and again we find a single or several layers of pavement epithelium. There may be in the same cyst cylindrical epithelium at one part and pavement at another, as shown by Lebedeff[1] and in three of Dr. Graefe's cases. After describing their anatomy, our author discusses the different opinions that have been entertained as to their origin. Klebs looks upon them as dilated lymphatic vessels, for the reason that he has found them lined with lymphatic endothelium. Dr. Graefe has only been able to find records of three cases in which the interior had such a covering; and even in them he does not think that the inference follows, that the cyst must have arisen by dilatation of a lymphatic vessel, because Lebedeff[1] has shown that cylindrical may, in these cysts, become changed into pavement epithelium. For the rare cases in which the cyst is without any epithelial lining, Dr. Graefe accepts Winckel's suggestion, that they may be merely spaces in the submucous connective tissue resulting from œdema, injury, or hæmorrhagic effusions. Cysts provided with an epithelial lining he regards as retention cysts, due to occlusion of the orifices of vaginal glands. He accepts the evidence brought forward by Von Preuschen as to the occasional existence of glands in the vagina. He points out that there is a stage in the development of the vagina in which it is lined by cylindrical epithelium, and refers to a case reported by Dr. C. Ruge, in which that observer found a small cyst on the vaginal portion of a fœtus of four months' development. Dr. Graefe therefore puts it, that the membrane lining a vaginal cyst, in producing cylinder epithelium, is "true to its embryonic tradition." There are, however, also cases in which the interior of the cyst presents a structure identical with that of the vagina itself. Of such, our author thinks Veit's conjecture a probable explanation: viz., that they are formed out of remains of the duct of the Wolffian body. Freund has suggested that some cysts may be rudiments of the ducts of Müller; and Dr. Graefe thinks this explanation applicable to one of his cases, in which there were six cysts, arranged in a row one behind the other. Another of his cases, in which there were three cysts, but not serially arranged, he thinks may be accounted for by the combined hypotheses of Veit and Freund.

In the same number of the *Zeitschrift* we find a short paper by Dr. J. Veit, published as a kind of appendix to that of Dr. Graefe, in which is described a case of a vaginal cyst of unusual size, as large as a child's head, projecting from the vulvar orifice in such a manner as at first sight to resemble prolapsus; and above reaching to the broad ligament. Dr. Veit thinks it probably originated in the remains of the Wolffian duct.

The Pathology of Hemichorea.—An interesting case of this affection is published by M. Mabboux, in the *Revue de Médecine* for December, 1883. His patient was a young soldier, aged twenty-three, who had been for some time under treatment for melancholia with various delusions. One morning he was discovered to have hemichorea of the right side, more marked in the arm than leg; twitching of the right side of his face had been observed occasionally during the few preceding days, but no importance had been attached to it. A careful examination of the patient elicited the fact that there was neither paralysis nor anæsthesia of the affected limbs, nor was any cause found for the movements. From this time the patient rapidly grew worse, the movements became more violent, the melancholia more intense, and he died sixteen days after the hemichorea was first observed. The author on repeated occasions examined the patient, but never found paralysis or anæsthesia. On examination a blood clot was found in the left lenticulo-optic region, surrounded by a zone of softening; the hæmorrhage involved the internal capsule, but not the most posterior

[1] *Medical Times and Gazette*, 1883, Vol. I., p. 13.

portion of it, invading also the postero-external part of the optic thalamus and the tail of the corpus striatum. The mental symptoms were fully accounted for by a tolerably extensive chronic fronto-parietal meningo-encephalitis. M. Mabboux explains the absence of hemiplegia by the slight degree to which the corpus striatum and optic thalamus were involved, and the absence of anæsthesia by the fact that the most posterior portion of the internal capsule was intact. But it seems to us that too much stress ought not to be laid upon the supposed absence of hemiplegia and hemianæsthesia in this case, for accurate observation on either of these points was impossible, at any rate during the last week of the patient's life.

PROPHYLACTIC TRACHEOTOMY IN EMPHYSEMA.—Dr. H. Schmidt relates the case of a man in whom emphysema ensued some hours after his receiving a wound in the neck, and spread so rapidly, especially in the vicinity of the larynx, that suffocation become imminent. The larynx was opened below the cricoid cartilage, and as soon as a tube had been introduced (which was done with some difficulty) breathing became entirely tranquil. By the third day all traces of the emphysema had disappeared, and the wound of trachea healed by the twelfth day.—*Betz Memorabilien*, 1883, No. 7.

THE TOTAL DESTRUCTION OF HUMAN BODIES.—M. Aimée Girard having lately proposed at the Académie des Sciences the destruction of the bodies of animals dying of virulent diseases by means of sulphuric acid (as their interment does not always secure from the danger they may cause), M. Régnard resolved to try the effect of this substance on the human subject. His experiments with the bodies of new-born infants and fœtuses have been completely successful, and would no doubt be equally so if tried on the adult. To the body of an infant he adds about double its weight of the sulphuric acid of commerce, and after 24 or 30 hours of maceration, not a vestige of the body remained —the decomposition having taken place silently and without any smell. Neither the microscope nor the test-tube can detect the slightest trace of the body, beyond the presence of some fat, phosphoric acid, and nitrogen. M. Régnard points out how easily a body may be made away with by means of a substance so easily procured, and suggests that some restrictions should be placed on its sale.—*Revue Méd.*, Dec. 1.

REPORTS OF SOCIETIES.

SOCIETY OF MEDICAL OFFICERS OF HEALTH.

FRIDAY, DECEMBER 21ST.

Dr. DUDFIELD, President, in the Chair.

[SUGGESTIONS FOR THE AMENDMENT OF THE ARTISANS' DWELLINGS ACTS.]

Dr. TRIPE read a paper on the above subject. The improvement of the dwellings of the poor, on which so much had been written and said of late, was, he held, a question essentially belonging to the Medical Officer of Health, since it was his representation alone which could set the law in action, whether for the improvement or the demolition of the premises concerned; and if, as Dr. Tripe believed, the present state of the law and the course of procedure were defective and inconvenient, it was the duty of the Society to point out the directions in which they might best be amended. First it seemed to him a serious defect that when actual demolition was the only practicable course, the work should be entrusted to different authorities proceeding under different acts according as the area were large or small, the former being cleared by the Metropolitan Board of Works at the expense of London generally, and the latter by the vestry or local board at the cost of the parish or district. He thought that wherever total demolition, whether of individual houses or of large areas, was imperative, it should be carried out by a single authority, and the cost defrayed from a single source; what the authority should be, he would leave to our legislators, provided only it were one representing the entire metropolis, while mere repairs and improvements might be left as at present to the local authorities. The question was complicated by the fact that while the inhabitants of these houses and areas did not as a rule earn more than 15*s.* a week, the dwellings now erected in their place were let at an average rent of 4*s.* 4*d.*, and therefore were taken at once by persons earning 24*s.* or more. The population for whom provision must be found was composed not only of the labouring poor, and those who picked up a living around the docks and markets, but of costermongers and street dealers, for whose donkeys and barrows accommodation must be made, with others who would not submit to the restraint imposed in model dwellings, and lastly, the filthy and destructive. The latter either still further overcrowded adjacent or similar districts, or were dispersed and perhaps improved, but the labouring poor must live in the immediate neighbourhood of their work and could not pay more than 2*s.* weekly, if so much, for which they had to be content with the wretched accommodation of a single room, or even only a part of one. Landlords had been unfairly blamed for the state of these tenements, but in fact the cost of keeping such places in repair, owing to the habits of the occupants, was so great, and defaulters were so many, that comparatively high rents were required to cover the losses incurred. The Medical Officer of Health might insist on repairs, whitewashing, &c., but the prevention of overcrowding presented great difficulties. Greater facilities for night visits, without which such overcrowding often could not be ascertained, were urgently required. Dr. Tripe would also propose that a landlord might be enabled to obtain from a magistrate an order for the speedy eviction of a tenant on the certificate of the Medical Officer of Health, and his own oath, that a room or house was unfit for human habitation from dirt, dilapidation, or overcrowding. If he neglected to avail himself of such power he would forfeit all sympathy when penalties were imposed on him on account of the condition of his property. Houses capable of being rendered habitable by simple alteration or repair should be dealt with by the local authority, and those requiring demolition by the central power, the certificates of the Medical Officer of Health and district surveyor determining the class to which they belonged; but a simplification of the present cumbrous machinery and enormous expense of compulsory purchase and arbitration was necessary. No house should be allowed to be occupied after having been legally condemned even pending an appeal. Summary powers should therefore be given for closing not only such houses, but also those where a landlord had neglected to carry out an order for repairs to be done within a certain time. Demolition, however, was but the first step; the problem was how to provide fresh dwellings in the place of those pulled down, and for the same class of persons. Neither the central nor the local authority could undertake the work without pecuniary loss to the ratepayers or suspicion of "jobbery." Public bodies, too engaged in other duties, could not exercise the requisite supervision of house property. State loans would involve needless expense in materials and construction, which would be required to be of the best, and unaided private enterprise would be insufficient to meet the need. The only alternative seemed to be the co-operation of persons willing to take shares in building houses suitable for the classes in question, and content with dividends not exceeding 3 or 3½ per cent., which was all that could be expected in London, even if the ground floors were let out as shops. These considerations, however, did not fall within the field of work of the Medical Officer of Health, and were mentioned here only to show the difficulties surrounding the question. Houses capable of improvement could be dealt with by existing acts, but increased powers must be given to the sanitary authorities, and orders should be obtainable from any two local justices, for at present there was too great delay in the issue of such by the police magistrates, a fortnight often elapsing after an application for an order at the Worship Street Court, and the hearing was again frequently adjourned from press of business. Further suggestions made by Dr. Tripe for dealing with this kind of property were as follows:—

The names and addresses of the actual owners, as well as of the legal owners, *i.e.*, persons receiving the rents, of all

houses let in lodgings or occupied by the poor, including all houses under £20 per annum, should be registered with the local authority, and such houses should be visited by an inspector at least twice a year, or oftener in case of complaint. Notices should be served on owners for all necessary improvements, and enforced under the 35th section of the Sanitary Act: the regulations under this clause being made uniform for the whole metropolis instead of being as at present left to the discretion of each local authority. If the owner neglected to comply with the order by a given day, he should be subject to a penalty of, say, 5*s.* per day during such neglect. If he after being summoned still made default, the local authority should have power to close the house or room. No appeal should be allowed against carrying out ordinary sanitary work, as repair or cleaning of premises and drains, or providing proper water supply to closets, and a separate supply for domestic use, but only in cases of structural improvements and the construction of drains. As regarded a separate water supply for drinking and domestic use, apart from that to the closets, the local authorities at present possessed no powers, though it was much to be desired that such were enforced in houses of every class. It would be well if regulations were made affecting all houses alike, prohibiting all direct connection of waste and sink pipes with the drains, and requiring in all new houses proper ventilation and interception of the house drains from the sewer, and the substitution everywhere of better forms of traps for the objectionable bell; and all persons wilfully damaging closets, traps, &c., should be summarily compelled to make good such damage.

Lastly, to determine overcrowding, some limit of cubic space per head must be fixed: this should not be too high, so as to raise the rent, or so low as to be injurious to health; 350 cubic feet for each person over twelve years, and less for children, would appear unobjectionable. If this were required, there would be no reason why several persons of different families, if of the same sex, should not occupy a single room, but indecent occupation by persons, even of the same family, ought to be put down.

Mr. WYNTER BLYTH gave an account of the work done in the parish of Marylebone under the Artisans' Dwellings Act during his tenure of office.

In the discussion that followed, Dr. EDMONDS, of St. James', Westminster, Dr. DIXON, of Bermondsey, and Mr. LOVETT, of St. Giles', as well as Mr. Greenwell, vestry clerk of Marylebone, Mr. Jones, district surveyor of St. Giles', and other gentlemen, took part. Agreeing entirely with the recommendations made by Dr. Tripe, they insisted that all improvements recoiled on the poor, whom they were intended to benefit; the cleared areas being subsequently occupied by a better class, and landlords recouping themselves for sanitary improvement of houses by raising the rents out of all proportion to the outlay.

Dr. DIXON complained of the unreasonable delay of the Metropolitan Board of Works in dealing with unhealthy areas unless their clearance would afford opportunities for the erection of warehouses or the opening up of better routes for traffic, instancing an area in his own district which he represented eight years ago, but as to which they had as yet taken no steps, the area in question having meanwhile nearly disappeared by the erection of a Board School, the falling down of some houses, &c. He expressed a strong feeling that the possession and letting of insanitary dwellings should be made penal in itself, and a fine of from 10*s.* to £5 imposed on the *agent*, since the landlord, if an absentee, might be ignorant of their state. No rent should be charged until the repairs ordered had been carried out, nor, he thought, should the rents be raised in consequence until after the expiration of a year.

Dr. EDMONDS suggested the utilisation for the class of dwellings required of the sites of the metropolitan workhouses, which might well be removed to suburban districts.

Dr. SAUNDERS, of West Herts, called attention to the Labouring Classes Lodgings Acts, of the existence of which many members were unaware, and which had remained a dead letter, though empowering local authorities, with or without State aid, to provide such dwellings, either by building them on lands purchased or leased by them, or by acquiring and improving existing tenements.

MEDICAL NEWS.

APOTHECARIES' HALL. — The following gentlemen passed their examination in the Science and Practice of Medicine, and received Certificates to Practise, on Thursday, 27th December, 1883:—

Edwin Alfred Bennett, Cornwall-road, Bayswater, W.
Herbert Crowley Dent, Wood-street, Woolwich.
Alfred Cromwell Frames, Belsize-park, N.W.
Charles Leopold Hudson, Bungay, Suffolk.
Laurie Asher Lawrence, Belsize-avenue, N.W.
Edward John Lewis, Great Coram-street, W.C.
George Lewis Rugg, Stockwell Villa, Clapham-road.
William Albert Wetwan, Tavistock-place, W.C.

The following gentlemen also on the same day passed their Primary Professional Examination:—

George Douglas Hunter, St. George's Hospital.
Edwin Charles Tatam, King's College.

THE BOWER AND KEATES' CASE.

At a Meeting of the Committee, held on Jan. 3rd, 1884, at 8.30 p.m., present Sir Wm. Jenner (in the chair), Dr. Wilson Fox, Dr. Moxon, Dr. Bright, Dr. Quain: *Resolved*, "That the Committee having obtained Subscriptions sufficient to meet the legal expenses incurred in the case of Messrs. Bower and Keates, beg to intimate that the list will be closed on Saturday the 5th inst. They will, however, be glad to receive further signatures to the Memorial.

F. A. MAHOMED, R. W. BURNET, } *Hon Secs.*

WE have received, too late for insertion in full in the present issue, the fourth list of contributions to the Indemnity Fund received up to Saturday, December 29. Since that date a still larger number of replies have, we hear, been sent in.

The following are the subscriptions above two guineas in the fourth list:—

Wilson Fox, F.R.S.	£10	10	0
W. S. Savory, F.R.C.S.	10	10	0
Sir Henry Thompson, F.R.C.S.	10	0	0
Thomas Smith, F.R.C.S.	10	0	0
Chas. A. Adey, M.D., St. Leonard's-on-Sea	5	5	0
Wm. F. Butt, Esq.	5	5	0
Ed. Clapton, M.D.	5	5	0
John E. Erichsen, F.R.C.S.	5	5	0
Barnard Holt, F.R.C.S.	5	5	0
Sir Edwin Saunders, F.R.C.S.	5	5	0
W. H. Walshe, M.D.	5	5	0
E. G. Barron, Esq., Plymouth	5	0	0
W. W. Kershaw, Esq., Surbiton	5	0	0
A. Farre, M.D.	3	3	0
Ed. Lund, F.R.C.S., Manchester	3	3	0
W. S. Playfair, M.D.	3	3	0
Wm. Priestley, M.D.	3	3	0
Septimus Sibley, F.R.C.S.	3	3	0
Edgcombe Venning, F.R.C.S.	3	3	0
John Wood, F.R.S.	3	3	0
J. M. Bright, M.D.	2	12	6
J. J. Eyre, Esq.	2	12	6

The name of Sir Andrew Clark, Bart, £10 10*s.*, was accidently omitted from the first list.

APPOINTMENTS.

GARDNER, P. H., M.R.C.S.—House Surgeon to the Royal Portsmouth, Portsea, and Gosport Hospital, *vice* W. C. Beevor, M.B., resigned.

GRIFFIN, JOHN, M.B., C.M. Ed.—Senior House Surgeon to the Royal South Hants Infirmary, *vice* H. Wynter Shettle, M.R.C.S., L.R.C.P., resigned.

GUNN, CHR., M.D.—Surgeon to the Jervis Street Hospital, Dublin, *vice* J. E. Kelly, resigned.

HERON, G. A., M.D.—Physician to the City of London Hospital for Diseases of the Chest, *vice* E. L. Birkett, M.D., retired.

LIPSCOMB, A. A., M.R.C.S., L.S.A.—House Physician to the London Hospital, *vice* C. M. Chadwick, M.B.

MASON, S. R., M.D., F.R.C.S.—Master of the Coombe Hospital, Dublin, *vice* G. H. Kidd, M.D., whose term of office has expired.

MUMFORD, WILLIAM ELLIS, L.R.C.P., L.R.C.S. — Re-appointed Medical Officer of Health for the Pudsey Urban Sanitary District.

PULLIN, HARRY L., L.D.S. Eng.—House-Surgeon to the Dental Hospital of London.

SHAW, L. E., M.B.—House Surgeon to the Victoria Hospital for Children, Queen's-road, Chelsea.

WILLIAMS, J. F., M.R.C.S.—Assistant Medical Officer and Dispenser to St. Saviour's Union.

NOTES, QUERIES, AND REPLIES.

THE ROGERS TESTIMONIAL.

The following is the tenth list of subscriptions:—An Admirer of Disinterested Work (per *Lancet*), £5; J. Harris Ross, M.D., C.M., Brighton, £1 1s.; Daniel Iles, Esq., Fairford, 10s. 6d.; B. Powne, Esq., Chard, 10s. 6d.; F. J. Flower, Esq., Warminster, 10s.; Geo. Hepworth, Esq., Gloucester, 10s.; Dr. A. Robertson, Town Hospital, Glasgow, 10s.; Dr. Hugh McLean, Corbridge, 10s.; J. W. Wolfendale, Esq., Tutbury, 5s.; Jno. Russell, Esq., Neath, 5s.; Geo. W. Rhodes, Esq., Huddersfield, 5s.; Thos. Fuller, Esq., M.D., New Shoreham, 5s.; Dr. Nathan Hannah, Ashton-in-Makerfield, 5s.; Jno. Clare, Esq., Hamley, 5s.

TO THE EDITOR OF THE MEDICAL TIMES AND GAZETTE.

SIR,—Will you kindly inform me under what authority the College of Physicians of London confer a qualification in Surgery as well as in Medicine—that is, a double qualification—on gentlemen who obtain their licence.

1st January, 1884. I am, Sir, yours, &c., ENQUIRER.

[Licentiates of the Royal College of Physicians of London are legally entitled to practise surgery as well as medicine, by the Act of Parliament 32 Hen. VIII. cap. 40, Sec. 3, which runs as follows.—"And forasmuch as the science of physic doth comprehend, include, and contain the knowledge of surgery as a special member and part of the same: therefore be it enacted that any of the said Company or Fellowship of Physicians, being able, chosen, and admitted by the said President and Fellowship of Physicians, may from time to time, as well within the City of London as elsewhere in this realm, practise and exercise the said science of Physic in all and every his members and parts, any Act, Statute, or provision made to the contrary notwithstanding."]

Dr. Kinsky, St. Petersburg.—We regret not to be able to accept your proposal.

A. E., Burton-on-Trent.—Certainly not.

Dr. Thompson, Launceston Hospital, Tasmania.—Letter and enclosure received with thanks.

John Forster, Esq., Crafers, Adelaide, South Australia.—Letter and enclosure received with thanks. Orders may be drawn on any post-office.

COMMUNICATIONS RECEIVED—

The EDITOR, "BRITISH MEDICAL JOURNAL," London; Dr. W. E. STEAVENSON, London; HON. SECRETARY, OPHTHALMALOGICAL SOCIETY, London; Dr. WYNTER BLYTH, London; THE HON. SECRETARY OBSTETRICAL SOCIETY, London; THE HON. SECRETARY MEDICAL SOCIETY OF LONDON; THE HON. SECRETARY HUNTERIAN SOCIETY, London; THE HON. SECRETARY CLINICAL SOCIETY, London; Dr. J. ALTHAUS, London; THE SANITARY COMMISSIONER FOR THE PUNJAUB, Lahore; THE SECRETARY SAMARITAN FREE HOSPITAL FOR WOMEN AND CHILDREN, London; THE SECRETARY THE HOSPITALS ASSOCIATION, London; THE HON. SECRETARY PATHOLOGICAL SOCIETY OF LONDON; Mr. FLETCHER, London; Mr. NOBLE SMITH, London; THE HON. SECRETARY MEDICO-PSYCHOLOGICAL ASSOCIATION, London; THE SECRETARY POOR LAW MEDICAL OFFICERS' ASSOCIATION, London; ASSISTANT SECRETARY ROYAL MICROSCOPICAL SOCIETY, London; Dr. ALFRED CARPENTER, Croydon; Mr. SHIRLEY MURPHY, London; Mr. T. M. STONE, Wimbledon; THE REGISTRAR-GENERAL FOR SCOTLAND, Edinburgh; Mr. W. ROBINSON, London; Mr. PIETRO MICHELLI, London; Dr. WHITLA, Belfast; Dr. W. DOMETT STONE, London; Dr. FOWLATT, Paris; Dr. ANDREW WILSON, London; REGISTRAR-GENERAL FOR ENGLAND AND WALES, London; Dr. J. W. LANGMORE, London; DIRECTOR OF THE ANTHROPOLOGICAL INSTITUTE, London; Mr. JAMES DIXON, Dorking; THE EDITOR OF "RUSSIAN MEDICINE," St. Petersburg; Mr. E. POCKNELL, London; Dr. J. W. MOORE, Dublin; THE SECRETARY APOTHECARIES SOCIETY, London; HON. SECRETARIES ODONTOLOGICAL SOCIETY OF GREAT BRITAIN, London; HON. SECRETARIES EPIDEMIOLOGICAL SOCIETY OF LONDON.

BOOKS RECEIVED—

Exsudatio Peritonitis, von Dr. Hermann Vierordt—The Life and Work of St. Paul, by F. W. Farrar, D.D.—Elements of Human Physiology, by Henry Power, M.B., F.R.C.S.—Water, by P. A. Maignen—Braithwaite's Retrospect of Medicine, Vol. LXXXVIII. —Pharmacy, Materia Medica, and Therapeutics, by W. Whitla, M.D.—Diseases of the Eye and Eyelids, by Louis H. Tosswill, B.A., M.B.—Life-History Album, by Francis Galton, F.R.S.—Record of Family Faculties, by Francis Galton, F.R.S.—On Life and its Lessons, by J. G. Davey, M.D.—The Surgical Treatment of Tumours, &c., by Walter Whitehead, F.R.C.S., and Bilton Pollard, M.D., B.S., F.R.C.S.—A Plea for the Cure of Rupture, by J. H. Warren, A.M., M.D.—Insanity, by T. R. Buckham, A.M., M.D.

PERIODICALS AND NEWSPAPERS RECEIVED—

APPOINTMENTS FOR THE WEEK.

January 5. *Saturday* (*this day*).

7. *Monday.*

ODONTOLOGICAL SOCIETY, 8 p.m. Annual General Meeting; election of Officers and Council. Casual communications by Mr. Morton Smale, Mr. Storer Bennett. Paper by Mr. Bland Sutton, "On Comparative Dental Pathology." Valedictory address by the President.

THE MEDICAL SOCIETY OF LONDON. Mr. R. Brudenell Carter will deliver the First Lettsomian Lecture, subject—"Modern Operations for Cataract."

8. *Tuesday.*

ANTHROPOLOGICAL INSTITUTE OF GREAT BRITAIN AND IRELAND, 8 p.m. Mr. H. H. Johnston, "On the Ethnology of the Congo and South Western Africa."

ROYAL MEDICAL AND CHIRURGICAL SOCIETY, 8.30 p.m. Mr. F. Treves, "On the Direct Treatment of Spinal Caries by Operation." Dr. Radcliffe Crocker, "Three Cases of Xeroderma Pigmentosum (Kaposi)."

9. *Wednesday.*

EPIDEMIOLOGICAL SOCIETY OF LONDON (11, Chandos-street, Cavendish-square), at 8 p.m. Surgeon-General Hunter, M.D., "On the Origin of the Cholera Epidemic of 1883 in Egypt."

ROYAL MICROSCOPICAL SOCIETY (King's College), 8 p.m.

OBSTETRICAL SOCIETY, 8 p.m. Specimens will be shown. The following Papers will be read:—"Observations of Puerperal Temperatures," by Dr. E. S. Tait. "On the Corroding Ulcer of the Os Uteri," by Dr. J. Williams.

HUNTERIAN SOCIETY (7 p.m. Council), 8 p.m. Mr. Reeves, "The Treatment of Rectal Stricture, with special reference to Inguinal Colotomy." Mr. Charters J. Symonds—"The Reliable Signs of Fracture of the Neck of the Femur."

10. *Thursday.*

OPHTHALMOLOGICAL SOCIETY OF THE UNITED KINGDOM, 8½ p.m. Living Specimens, 8 p.m. Discussion, "On Sympathetic Ophthalmitis," adjourned from last meeting. Simeon Snell, "Two Cases of Retinal Glioma, in one of which Shrinking of the Eyeball occurred without Perforation." Dr. G. A. Brown, "A Case of severe Conjunctivitis with Formation of Membrane on the Cornea, caused by Whisky thrown in the Eyes." Henry Eales, "Complete Paralysis of Convergence and Accommodation in a girl æt. 13." J. B. Story, "On the Treatment of Cystoid Cicatrix." A. Stanford Morton, "Congenital Absence of Lacrimation in a Boy." M. M. McHardy, "Some Clinical Observations which appear to Indicate a Means of Reducing the Danger from Malignant Glaucoma while Increasing the Efficacy of Iridectomy in the Treatment of Chronic Glaucoma."

11. *Friday.*

CLINICAL SOCIETY OF LONDON.—Annual General Meeting for Election of Officers and Council. Papers:—1. Dr. J. K. Fowler, "On a Case of Subcutaneous Nodules;" 2. Dr. Coxwell, "On a Case of Cortical Tumour with Unusual Frequency of Epileptiform Attacks;" 3. Dr. R. J. Lee, "On a Second Case of Creeping Eruption.

MODERN OPERATIONS FOR CATARARCT.

The Lettsomian Lectures Delivered at the Medical Society of London,

By R. BRUDENELL CARTER, F.R.C.S.,

Ophthalmic Surgeon to St. George's Hospital.

Lecture I.

When I first became acquainted with the honour which had been conferred upon me by the Council of the Medical Society of London, by my election to the office of Lettsomian Lecturer, my thoughts naturally ranged over the whole field of ophthalmic surgery, in search of some topic which might furnish me with sufficient material for discourse. I have been able to discover nothing of greater promise than the operative treatment of senile cataract, an affection which still levies its annual tribute of victims, and which the advances of therapeutical science have done nothing either to prevent or to cure. In the character of the malady itself, there is something which appeals with irresistible force to our most kindly sympathies. At a period of life when the physical powers are beginning to decay, when the approach of old age is making itself felt by the gradual curtailment of all pleasant activities, and when the resources afforded by vision are therefore relatively increased in value and importance, these resources are themselves threatened by a degeneration of such gradual progress that its oncoming cannot be overlooked by the sufferer, to whom it brings home the anticipation of loss of sight, in a manner so forcible as to become almost as distressing as the reality. At a period not far distant in actual time, even although, when measured by the growth of modern improvement, it may now almost be called remote, it was held as a canon of surgery that no operation for the removal of cataract should be performed so long as the state of the patient admitted of being made worse by failure; and the long misery of suspense, which this practice entailed upon numbers of people, received but a poor compensation from the completeness of the relief which, in cases of favourable issue, was eventually afforded. The operation for cataract was occasionally brilliantly successful, and was frequently followed by great improvement of sight; but yet, in a deplorable proportion of cases, it led only to complete and irremediable failure. For reasons which I will presently assign, I do not think that any of the statistics of cataract operation prior to the introduction of the ophthalmoscope can be regarded as quite trustworthy, or can be used with entire satisfaction as the basis of a comparison between former times and the present; but it was a common estimate, when I commenced the practice of ophthalmic surgery, in 1859, that about 15 per cent. of all extraction cases ended in total loss of sight, and that in about 25 per cent. more the results were imperfect, leaving only about 60 per cent. of the whole which were fully satisfactory. There can be no doubt that the average results of the present day are greatly better than this; and also that we have gained in a direction almost equally important to our patients, by being able, with safety and propriety, to operate at a much earlier period than was formerly customary, and thus not only to deal with younger and stronger people, but also to relieve these people from anxiety about the

issue before the defect of sight amounts to actual incapacity. It will be my endeavour, on this and subsequent evenings, to trace out the steps by which these improvements have been attained, and the extent to which they have been carried; and I trust to be able to establish the position that ophthalmic surgeons have not only profited by the better means of exploration and diagnosis of which they have in recent years become possessed, but also that they have laboured with zeal and success to keep pace with the advances which have been made in general surgery, and to render their treatment of long familiar conditions more successful than heretofore. The assertion that ophthalmology has been revolutionised as a branch of science is one the truth of which will be universally admitted; but the assertion that it has also been revolutionised as a branch of surgery is one which some among my hearers may regard as still requiring the support of evidence. If such there be, I will do my endeavour to satisfy them.

I have just said that none of what may be called the earlier statistics of cataract extraction appear to me to be satisfactory; and I am afraid that I must extend the remark to some of more recent date. Prior to the use of the ophthalmoscope, the diagnosis was extremely difficult and uncertain; and I have no doubt that many of the instances of reputed failure were not cases of cataract at all. If we turn to any moderately old treatise upon the subject, we shall find elaborate rules for distinguishing cataract from glaucoma, the real or supposed differences between them, but more frequently the latter, being placed in parallel columns for the purpose of ready comparison; and it is impossible but that errors must have been of frequent occurrence. Even now, I sometimes see cases in which, but for the help afforded by the opthalmoscope, I might possibly feel some doubt; and, as a matter of fact, I was once asked by a London physician, well known to many of us, to perform extraction for a lady whose lenses were as transparent as his own, and in whom the appearances by which he had been misled were produced by the character of the light-reflection from the fundus of the eye. When we come to more modern times, this source of error no longer exists, for the cloudiness or transparency of the lens can be determined with the ophthalmoscope almost by a glance; but we have been brought face to face with conditions of a totally different order. We have been in the presence of unquestionably improved methods, and in the presence also of a vast number of small modifications in points of detail, each suggested by some operator, often of very limited experience, who claims to have improved the operation of extraction by its means, who wishes what he is perhaps pleased to describe as "his" method to be called after his name, and who is almost bound to justify his claim to have effected an improvement by publishing better statistics than those of his contemporaries or of his predecessors. In England there has been little or nothing of all this; but in some countries a good deal, and the foreign constructors of statistics have well-nigh come to occupy the position of the manufacturer who adopted, in the furnace of his steam-engine, all the patented contrivances for diminishing the expenditure of fuel. He adopted the improvement which saved fifty per cent., and the improvement which saved forty per cent., and the others which saved thirty, twenty, and ten, respectively; until at last he not only ran his engine for nothing, but actually derived a handsome income from the payments made to him by coal dealers as a recompense for keeping it going. In like manner, a due regard for accuracy would certainly compel some of the originators of improved methods to confer normal vision upon three eyes for every two upon which they were called to operate. As a matter of fact, however, they hardly go so far as this; and some of the gentlemen whose exploits are chronicled in Germany or in America are so modest that they profess to fall short of a perfect result in at least one per cent. of their cases. Their scrupulous veracity reminds me of the American sportsman, who related how he had killed 999 wild ducks by a single discharge of a swivel gun; and who, when asked why he "did not say a thousand at once?" replied that he "would not peril his immortal soul for the sake of one duck!" I feel strongly that the time has come for an endeavour to explode some of the pestilent nonsense which has been talked and written on this subject. The operation of extraction has, no doubt, been greatly improved in directions which have added much to the general proportion of success. The fact remains that the patients on whom it is performed are, upon an average, 70 years old or more; and that the opacity of the lens is itself a degenerative change which indicates failure of nutrition. It will be associated, in a considerable number of instances, with failure of nutrition in other directions also, with arterial degeneration, with cardiac weakness, or with renal inadequacy; and these conditions must militate against the completion of the processes of repair which are essential to the success of any operation, be it what it may. We may be fairly content to have attained to methods of procedure which reduce the demand upon the reparative powers to the lowest point; and we cannot expect to operate without having any demand at all, or that this demand shall invariably be responded to in the right manner and at the right time. An operator who aimed at a very large percentage of success would have to select his cases with extreme care; and to do this would be to refuse relief to numbers of patients who ought to have at least the chance of obtaining it. Even when the selection had been made, he would still be exposed to a class of occurrences which can only be described as accidents, to accidents from vomiting, to accidents from intra-ocular hæmorrhage, to accidents from spasm of the recti muscles; and some of these things would now and then turn the scale against him. It is far better, in my judgment, because far more truthful and more manly, to admit that in the extraction of cataract, as in every other human undertaking, "time and chance happeneth to all." The prospects of success are sufficient to afford great encouragement to patients; the prospects of failure are certainly such as to require to be taken into account.

Among recent statistics which strike me as being reasonable and trustworthy, although in some respects very incomplete, I may mention those furnished by the annual reports of the New York Ophthalmic Institute. Taking the last two years, these reports show a total of 144 operations, by Von Graefe's method, for the extraction of senile cataract. The results are stated to have been "good" in 128 cases, or 88·9 per cent.; "moderate" in 12 cases, or 8·4 per cent.; and "failure" in 4 cases, or 2·77 per cent. The value of the figures is much diminished by the absence of any statement of the precise quality of the vision which is described as "good" or "moderate" respectively; so that cases may have been included in the former category which would by some surgeons have been relegated to the latter, and cases which were hardly distinguishable from failures may have been described as moderately successful. It is safe to assume, however, that, out of 144 eyes, 140 were left in an improved condition by the operation; and that in only four was the sight irretrievably lost.

The analogy may at first sight appear to be a somewhat strained one, but the improvements which have been effected in the extraction of cataract often remind me of those which have been effected in the operation of ovariotomy. In the latter there is, of course, a question of mortality which does not complicate the

former; but, otherwise, the resemblance between the two histories is very close indeed. In both of them the efforts of the surgeon are directed to the removal of a substance from within a closed cavity, which is liable, when wounded, to become the seat of severe inflamation; and in both an increased measure of success has been attained by the careful observation and study of all circumstances which tend towards an unfavourable issue, and by bringing these circumstances under control. In both a main feature of the improvement has been the diminished size of the external wound, together with the adoption of precautions for rendering the absolute exit of that which is taken away a process less irritating or injurious to the textures through which the removal is effected. The antiseptic methods which, according to some operators, have exerted a favourable influence upon ovariotomy are not available, or only in a very limited degree, in cataract cases; but the general conditions by which healing is promoted require to be equally borne in mind in the management of both. The details of ovariotomy are familiar to all who hear me; and I think an outline sketch of the differences between ancient and modern cataract extraction will fully bear out what I have ventured to assert with regard to the resemblance which exists between the two kinds of surgical improvement.

For about one hundred and ten years prior to 1860, the method of cataract extraction had remained substantially unchanged. It was the operation of Daviel, modified only by the introduction of Beer's triangular knife to supersede that which Daviel had originally employed; and it displaced the still earlier operation of depression or couching, in which the dislocated lens was apt to act as a foreign body, and to set up destructive inflammation after a longer or shorter period of time. In Daviel's operation, which of late years has been commonly distinguished as "flap" extraction, the knife was introduced through the cornea, on its horizontal meridian, about one millimetre in front of the corneo-scleral junction, and was carried across the anterior chamber, with the cutting edge upwards, and the plane of the blade parallel to that of the iris, to a corresponding point on the opposite side of the cornea, at which it was brought out again by a counter-puncture, and was then pushed straight on so as to divide the whole of the tissues between the wound of entrance and the wound of exit. When this was correctly done, the result was a semi-circular section of the cornea, concentric with, and about a millimetre within, its actual periphery, so that the greater part of its upper half was detached in the form of a flap; and the triangular shape of the blade, which always filled its own wound as it advanced, permitted the aqueous humour to be retained until the section was almost completed. The next step was to divide the capsule of the lens by a curved needle introduced through the wound, and the next was to press out the lens, which had first to stretch and pass through the natural pupil, and then to emerge from the eye through the corneal section. When all this had been accomplished, the lids were closed, and, as a rule, were not opened for any purpose of examination until after the lapse of from five to seven days.

Even after the introduction of anæsthetics, they were but seldom employed in flap extraction, chiefly because the large size of the external wound rendered vomiting an extremely dangerous occurrence; and one consequence of the want of them was that accidents were frequently produced by the unsteadiness of the patient. The eyeball was originally not fixed or held, but only supported against the knife by the fingers of the free hand of the surgeon; and hence the precise line of incision was in a great degree dependent upon the conduct of the patient. If he struggled, or rolled the eye upwards, both the points of puncture and of counter-puncture and the line of section were liable to be misplaced, the former being either too high or too low, too near the centre of the cornea or too near the sclerotic, and the latter either too far forward or too far back, thus either encroaching too much upon the cornea or entering upon vascular tissue beyond its margin. From the same cause there was frequent failure to retain the aqueous humour for a sufficiently long period; and, when it escaped prematurely, the iris was apt to fall over the edge of the knife, and to be wounded more or less severely. The pressure by which the cataract was extruded often caused the extrusion of more or less of the vitreous body; and many other accidents, too many indeed to enumerate, were prone to occur.

Of these several accidents there was scarcely one which was not calculated to impair, while many were calculated to destroy, the character of the result. If the patient were unsteady, one of the first consequences was likely to be a misplaced counter-puncture. When this was made too low, so that more than half of the cornea was severed from its attachment, the exit of the lens was facilitated, but at the same time the risks of loss of vitreous, and the risks of sloughing of the cornea, were increased. When the counter-puncture was made too high, or too far forward, the corneal section would probably be too small for the free exit of the lens. The operator was armed against this contingency by an apparatus of "secondary knives," "right and left-handed scissors," &c., &c., for the enlargement of the section; but the results of being compelled to have recourse to these weapons were often disastrous. When correctly performed, the operation was bloodless; but, if the iris were wounded by falling over the edge of the knife, or if the corneal section were carried too far back, so as to trench upon the corneo-scleral junction and to divide vessels, in either case the anterior chamber became filled with blood, which obscured the pupil, and rendered the subsequent steps difficult and uncertain. If the upper part of the corneal section descended too low, in consequence of the edge of the knife being directed forwards, not only was the wound likely to be too small for the exit of the lens, and thus, by calling for increased pressure, to promote the loss of vitreous, but it was also liable, in cases which otherwise terminated favourably, to occasion distortion of the corneal curvature by the contraction incidental to healing, and thus very seriously to diminish the resulting acuteness of vision. Loss of vitreous was always a grave disaster. Whenever it occurred, it lifted the iris between the lips of the wound, and was followed by iritis and closure of the pupil. In a certain proportion of such cases, more or less vision could be ultimately restored by a subsequent operation for artificial pupil; but, in the majority, a period of much suffering was the prelude to complete extinction of sight.

When all these shoals and quicksands had been avoided, when the corneal section had been correctly made, when the capsule of the lens had been divided without injury to the iris, and when the lens had been pressed out without either loss of vitreous or protrusion of the iris into the section, the risks of failure were by no means set aside. The eye was closed, the lids being generally fastened together by a strip of plaster, and it was not opened again for some days. About forty-eight hours after the operation, it was not uncommon for the lids to be a little swollen, and for a small amount of muco-purulent discharge, which rapidly assumed a purulent character, to make its appearance at their edges. These symptoms were, almost without exception, the precursors of suppuration of the eyeball, terminating, of course, in total destruction of the organ, which, after many days of acute suffering, shrivelled into a sightless button in the bottom of the

orbit. Very little was known about the origin of the changes which led to so disastrous a termination; for the rule of practice was to abstain from any examination of the eye until either fair success or total failure was sufficiently declared. It was believed that to separate the lids during the first two days would add to the risks of suppuration; and surgeons were content to learn that all was well from the absence of eyelid swelling; while, if such swelling occurred, they were fearful of aggravating the mischief, or of destroying any prospect of partial recovery, by an inspection of the inflamed tissues. The feeling was that it was better for the patient, and an addition to his chances, whether these were good or bad, that his eyelids should rest undisturbed; and, as the surgical traditions of this country place the welfare of the patient before every other consideration, undisturbed they were suffered to remain.

It is perhaps possible, however, for even a sound principle to be carried too far; and this one, in the case under consideration, was carried to the extent of depriving surgeons of all opportunity of observing the initial stages of mischief of a very grave character. Von Graefe was the first operator who departed from the accepted routine; for, being wishful to know why some eyes underwent suppuration, while others escaped, he adopted the practice of opening every eye daily, after extraction had been performed, so as to observe the first signs of suppuration and the precise locality in which they occurred. He succeeded in establishing two distinct varieties of the process, if so they may be called; or, at all events, two distinct classes of cases. In one, the initial phenomenon was iritis, commencing at the portion of iris opposite the section, at the part, in short, where the iris was most exposed to suffer bruising or compression during the exit of the lens. In cases of the other class, the initial phenomenon was necrosis of the cornea, produced by its extensive severance from the sources of its nutrition. There were, therefore, two possibilities to combat, the plastic inflammation, which, in the recently wounded eye, always led on to suppuration; and the direct necrosis which produced the same effect. As soon as Von Graefe's results were made known, and before he himself made any attempt to turn them to profitable account, Dr. Mooren, then of Crefeld, suggested that the risks of iritis from contusion might be diminished by the performance of iridectomy as a preliminary operation, to be followed by extraction after an interval of time; and he proceeded to put his suggestion into practice. His results were so excellent, that the pamphlet in which he published them was received, in Germany, with very general incredulity; insomuch that the author, referring to this incredulity in a second edition, made it a reason for publishing the name and address of every patient upon whom he had operated by his method, so that all who pleased might go and verify his statements. I may perhaps remark, in passing, that both the incredulity, and the means adopted to combat it, seem to me to indicate that the standard of scientific veracity is less high in some countries than amongst ourselves, and in some measure to justify the doubts which I have expressed concerning the trustworthiness of certain statistics with which the profession and the public have from time to time been favoured. However this may be, it soon became manifest, not only that Mooren had succeeded in diminishing the liability to iritis after extraction, but that his method, by permitting the escape of the lens through a smaller external wound, had also served, in an indirect manner, to diminish the risks of corneal suppuration. The cases on which he laid most stress were some successful operations upon very feeble and emaciated old women, in whom sloughing of the cornea would almost certainly have occurred, if they had been subjected to flap-extraction in the ordinary way.

Mooren's pamphlet reached me towards the latter end of 1862; and, in December of that year, I adopted his method, this being, I believe, the first time that it was used in England. The patient was an old man from whose right eye I had previously extracted cataract in the old-fashioned manner, and with complete success; so that I felt myself at liberty to use his left eye for what was then almost an experiment. There was a very general feeling, among those with whom I discussed the operation, that the quality of the visual result would be lowered by the iridectomy, as a consequence of the altered shape of the pupil; but I had the gratification of finding that this was not the case. The left eye made an excellent recovery; and the sight obtained from it was equal to that of the right eye, which had its iris unbroken, and its pupil central and circular. A single case could do nothing, of course, to prove the advantages of the new method of operating; but it did prove that the method was practicable, and that the result might be of the best kind. The interval between the iridectomy and the extraction, in my first case, was 14 days; but it was ultimately found better, by the general experience of operators, to prolong this interval to about six weeks.

A sufficiently extensive trial of Dr. Mooren's method may be said to have established three propositions:—1st. That the artificial coloboma iridis produced by the iridectomy afforded a safe way of exit for the lens, and that, by removing the upper part of the iris from injurious pressure, it to a great extent set aside the danger of iritis as a consequence of the final operation. 2ndly. That when the exit of the lens through the pupil was thus made easy, its ultimate exit from the eye could be effected through a smaller external wound than it had formerly been customary to employ, thus diminishing the dangers of corneal death as a consequence of the extensive severence of that membrane from the sources of its nutrition. 3rdly. That while the two principal sources of total and irretrievable failure were thus either set aside or greatly diminished, the visual results were nearly or quite as good as any which had been obtained, even in the most successful cases, from the employment of the old or prior form of the operation.

Mooren was speedily followed by other innovators, the most remarkable being Dr. Schuft, who afterwards assumed the name of Waldau, and who proposed to remove cataract by scooping it out of the eye with a little spoon, through a comparatively small wound at the corneal margin. If I remember rightly, Schuft did not propose to perform iridectomy, but to use his spoon through the natural pupil; but on this point I am not absolutely certain. He published some statistics which induced other surgeons to follow his example; and the chief thing worthy of note about his method was that it was extensively tried at the Royal London Ophthalmic Hospital, and that both Sir William Bowman and the late Mr. Critchett thought sufficiently well of it, at one time, to make endeavours to improve the form of the scoop. Schuft's scoop was a small oval spoon, with a margin all round perpendicular to its base. Sir William Bowman did away with the margin, excepting at the tip of the spoon, and there had it carried forward into a sort of point, as if to glide under or behind the lens more easily. Mr. Critchett also limited the margin to the front part of the spoon, but had it brought backwards towards the handle, in a fashion roughly resembling the toe of a slipper, or the barb of a fish-hook, as if to give it a better hold upon the further margin of the lens when in course of withdrawal. These modifications were not very important, but they were sufficient to show that English surgeons were from the first dissatisfied with the form of Waldau's instrument, although at one time prepared to admit the soundness of the principle on which it was based. Experience soon showed, however, that the

method of "outscooping" was beset by many dangers; and, after a comparatively short trial, it was abandoned even by most of those who had at first been its advocates. Coincidently with the general distrust of its value or safety came the announcement that Von Graefe was engaged upon the development of a new form of operation, from which great results were being obtained; and, after a short period, a description of this, under the name of "modified linear extraction," was given to the world. Von Graefe's plan essentially consisted in making an iridectomy the first step of the operation, instead of, as Mooren had done, a preliminary and distinct proceeding, and in placing his section in such a manner that the line of wound was entirely outside of the cornea, and in a plane which would pass through the centre of the eyeball. In his first attempts, he removed the lens by means of a small curved hook; but experience taught him to refrain, as much as might be possible, from the introduction of any form of traction instrument within the eye, and he ultimately brought out the lens by pressure alone, exercised below the cornea or upon its lower part, and assisted by a simultaneous gliding pressure upon the posterior lip of the wound with the back of a thin scoop, this gliding pressure being described by him as the "schlitten-manœuvre." Its object was not only to open the wound by holding back its posterior lip, but also to tilt the edge of the lens forwards, and so to assist it to clear all impediments to its free exit. As time went on, we heard less and less of the "schlitten-manœuvre," and more reliance came to be placed upon judiciously exercised direct pressure, made upon the lower part of the cornea by the back of a whalebone or tortoiseshell spoon, which was made to follow the issuing lens upwards as it passed through the section.

Von Graefe's section was made by puncture, counter-puncture, and division of the intervening bridge of tissue, by means of the slender straight knife now so widely known by his name. The centre of the section was just outside of the corneal margin, while its extremities were separated from this margin by an appreciable interval; and one advantage claimed for this situation was that the wound had no tendency to gape, but that its edges fell spontaneously into contact, and were placed in tissue possessing sufficient vascularity to promote rapid and easy healing. On the other hand, it was before long rendered manifest by experience that the situation, whatever might be its advantages, had also its peculiar dangers. If the section were at all unduly prolonged, or if either the puncture or the counter-puncture were placed at all too far back, the extremities came distinctly into the ciliary region, to which, indeed, they were always perilously near; and it is well known that wounds of the ciliary region have been fertile sources of sympathetic ophthalmia. Cases of this kind following upon extraction were before long reported; and I well remember, on seeking a consultation with Sir William Bowman concerning the first of these which occurred in my own practice, and on remarking to him that I had not seen one previously, his reply to the effect that he wished he could say the same. After awhile it came to be distinctly recognised, by those who had frequent opportunities of operating, that while a truly corneal section always involved more or less danger to the eye from sloughing or necrosis of that membrane, so a section entirely posterior to the cornea involved its own peculiar risks of plastic inflammation, with a possibility of extension to the sound eye. This contingency was, I need hardly say, even more serious than the other; and surgeons generally began to return towards the corneal section. It is surprising, within the narrow limits of the available space, how many differences in the precise position of the incision have been described, if not actually accomplished in practice, for it is one thing to lay down a line upon a diagram, and quite another to adhere strictly to it in the actual conditions of the operating couch. The late Mr. Critchett, with the happy practicality which was so conspicuous among his great merits, was at one time accustomed, whenever he was able to operate upon both eyes at once, to make a corneal section in one of them, and a slightly post-corneal section in the other. He held, doubtless with much correctness, that the circumstances which determined the occurrence of unfavourable results were possibly as much constitutional as local in their character, and that any individual patient was not likely to suffer, at the same time, from necrosis and from plastic inflammation. By making in one eye a section which had its chief risks on the side of necrosis, and, in the other, a section which had its chief risks on the side of plastic inflammation, he thought himself able to make almost certain of a good result in one or in the other; and, in carrying out this practice, it is manifest that he would generally be rewarded by a good result in both.

A method of operating which must not be overlooked was that of Pagenstecher, who advocated the extraction of the lens in its unbroken capsule. His plan was to make a rather large section, with a broad lance-knife, at the margin of the cornea, and an iridectomy of equal magnitude, and then, in some cases, the lens may be extruded, still within its capsule, by gentle pressure from the side of the corneal margin most remote from the incision. This only happens, manifestly, when the tenacity of the lens-capsule is greater than the strength of its attachment to the hyaloid membrane behind it; for, if the latter be the stronger, one of two results must follow. Either the hyaloid becomes ruptured at the zonule, and vitreous humour escapes before the lens, or the capsule itself yields to the pressure, and the lens escapes through the rent in the ordinary way. The latter event does not place the eye in any peril; and it permits the accomplishment of a successful ordinary extraction, the visual results of which are perhaps rendered somewhat less good than they might be by the large size and the downward position of the coloboma iridis. When the vitreous escapes, the consequences are more serious. Not unfrequently, the capsule yields also, and then the best attainable result is to leave behind in the eye more or less of the cortical substance, entangled by the more viscid vitreous body. Frequently, however, the lens shows no tendency towards emergence, but is rather inclined to recede within the eye as more and more vitreous passes away through the section. When this occurs, the surgeon has no alternative but to lift out the lens with a spoon, which the originator of the operation contrived for the purpose. Even then, the amount of vitreous lost is often considerable; and the use of a spoon or other traction instrument within the eye is a proceeding which should be avoided whenever possible. When Pagenstecher's operation succeeds well—which is chiefly in very aged people with dense and mature cataracts—its results are as good as can be desired; and the pupil, being perfectly free from every trace of opacity, displays a brilliancy of blackness which is not often witnessed as an effect of other methods. When the scoop is introduced, however, some of the cases in which success is at first obtained become afterwards obscured by a peculiar turbidity of the vitreous, which has been attributed to a chronic hyalitis; and it may be said, speaking generally, that the average of success has not been sufficient to satisfy the desires of surgeons. When employed only in selected cases—namely, in very old people whose cataracts are mature—the operation often succeeds extremely well; but even in them it has a drawback, in the shape of the very deep anæsthesia which is required in order to preserve entire passivity of the eye, since any contraction of its muscles might suffice to rupture the hyaloid, and to

*

expel vitreous through the large iridectomy and external section. The reason of the greater applicability of the method to the aged seems to be that in them, while degenerative processes have loosened the attachment between the lens capsule and the hyaloid, they have at the same time produced some thickening or condensation of the capsule itself, by which it is rendered at once more easily detachable from its connections, and more resistent under pressure.

The methods introduced by Jacobson, and by one or two others of less distinction, seem hardly to call for notice in the limited time at my disposal; but it is perhaps advisable to refer briefly to a group of operators who have distinguished themselves by the advocacy and practice of methods which seem to me to set all the principles of surgery at defiance. The first of this group was Dr. Kuchler, of Darmstadt, who extracted cataract by making an incision straight across the cornea, on its horizontal meridian, and by pressing out the lens through the natural pupil. He then returned to old ways by bandaging up the eye in many folds of plaster of Paris bandage, which were not to be removed for a week. I say of this operation, that it sets all the principles of surgery at defiance, and for these reasons:—In the first place, the ultimate visual result must be dependent on the integrity of the cornea and the unaltered character of its curves; and an operation which produces a horizontal corneal wound must necessarily be followed by an opaque line, more or less broad, along the track of the section, and by a modification of curvature, incidental to the contraction which attends or follows the completion of healing. In the next place, there are few sources of greater danger to the eye than adhesions of the iris, whether to the cornea or to the lens; and in this operation, the completion of the section permits the iris to fall forwards into contact with the posterior surface of the divided cornea, and thus, almost inevitably, to become adherent to it during the process of healing. As a matter of fact, both these occurrences were frequent in Dr. Kuchler's hands, so that, besides a large proportion of patients whose eyes perished, sooner or later, from the effects of the adhesions of the iris and of recurrent iritis produced by them, he had also a large proportion in whom the corneæ were converted, by a cicatricial contraction, into distorting media, through which no good vision could ever be obtained. Notwithstanding this, and notwithstanding the tolerably obvious necessity of such issues, the operation was one which could be performed with extreme facility, and this circumstance, no doubt, led some who should have known better to adopt or to modify it. Mr. Liebreich, for example, introduced to the profession in the St. Thomas's Hospital Reports, and I believe actually performed, what he called a "new" method of cataract extraction, which was, in fact, nothing more than a slight modification of Kuchler's proceeding. The section was made across the lower part of the cornea, instead of across the horizontal meridian, and a notch was cut out of the lower margin of the pupil, to give easier exit to the lens, but these were practically the sole differences. The corneal distortion certain to be produced was more in the lower half of the membrane, and less directly opposite the pupil. It was therefore likely to be somewhat less disturbing to distant vision; but more disturbing even than Kuchler's cicatrix in the act of reading, when the gaze is usually directed downwards. Inasmuch, moreover, as the majority of operations would be performed upon aged people, in whom the general activity of the body is somewhat curtailed, and to whom the power of reading is relatively increased in value, I am disposed to think that the chief difference between Liebreich's and Kuchler's methods is not in favour of the former. As regards liability to iritis and to the formation of adhesions, I should judge them to be much upon a level. Mr. Liebreich recommended his operation by the odd arguments that it was very easy of performance, and that all the instruments required for it might be carried in the waistcoat pocket. It is of course very easy to take a lens out of the eye if you make a hole large enough, and the practical question is rather what becomes of the eye after you have done so. In these days of antiseptic surgery, moreover, the waistcoat pocket would hardly be the receptacle one would select for a knife which was intended to penetrate the anterior chamber; and the method always appeared to me to be surpassed, both as regards simplicity and as regards ease and celerity of performance, by one with which I became acquainted when Surgeon to the Royal South London Opthalmic Hospital, where we were accustomed to describe it as the "marital" method. The patients were mostly of the female sex, and were persons in whom the lens had been expelled from the eye by the smart application to the margin of the orbit of the clenched fist of a male companion. The only instruments required were such as every man carries for daily use, and no pocket at all was needed to contain them. Some of the patients made excellent recoveries; and I have heard that the same assertion might be made with regard to those who have been operated upon after the manner of Mr. Liebreich.

The general results of the work of the last twenty years may, I think, be summed up by saying that the performance of iridectomy permits the escape of the lens through a smaller section, and also, by preventing bruising of the iris, diminishes the risk of inflammation of that membrane, an occurrence which, when it followed immediately after the operation, was always destructive to the eye. The smaller corneal or corneo-sclerotic section diminishes the risk of sloughing of the cornea; and in this way, by the diminution of the two chief dangers of the old operation, a notable increase in the percentage of success has been obtained. For several years after the general principle of these results was well established, surgeons were still more or less bound by the old rule of not operating until the cataract was "mature"—that is to say, until the opacity has extended to the whole of its cortical substance. In time, however, it came to be recognised that this long delay, which had been undoubtedly called for by the results of the contrary practice, as applied to flap extraction, might to some extent be departed from; and now, to the great benefit of many persons, it is customary to operate at any earlier period than would formerly have been prudent or right. Of the steps by which this progress has been attained, and of the degree to which it has been carried, it will be my duty to speak in the next lecture.

EXTRACT FROM A CLINICAL LECTURE ON TOBACCO POISONING.

By JONATHAN HUTCHINSON, F.R.S.,
Emeritus Professor of Surgery to the London Hospital.

In this connexion let me relate to you a case which is instructive, although not so well authenticated as to detail as I could wish. I had the narrative from a medical man of great intelligence, who was himself the subject of it. He told me that some years before I saw him, he had for some months been "nearly blind." He lost reading power and, "could scarcely recognise his friends." He consulted, separately, four distinguished ophthalmic surgeons. One said that he could find nothing amiss, but gave a gloomy prognosis. Another thought the optic discs pale, and another, that all that he could see were unusually large physiological cups. Two conjured him not to smoke; a third said he might

smoke as much as he liked, and another omitted any opinion on this point. He had been smoking very heavily, and drinking very moderately. The failure had begun whilst on a visit to Germany, when he had smoked still more than usual, but a mild tobacco. In spite of the advice given he did not, as he says, in any way diminish his smoking. He took strychnia until his muscles jumped, but was no better. On one occasion, whilst at his worst, he dined with a friend and took "quite as much champagne as a respectable person ought to do." This was against his usual habit, which was to be abstemious in wine. The result was that when he reached his home after the dinner, he found, to his delight, that he could read small print. In the morning, however, his sight was as bad as ever. At length he consulted a fifth specialist, who ordered him small doses of opium. Finding some, but not all the benefit he desired, be took not small doses, but large ones, and had the good fortune to have his vision steadily improve, until he could see again almost perfectly. He had some difficulty in leaving off his opium, but gradually diminishing the dose, he at length did so. Now Dr. —— assured me that he knew of no cause for this attack of amaurosis, nor of any explanation of its cure excepting that assigned. He had been in good health all the time, and neither before nor since had he suffered from any indications of nervous exhaustion. He was not overworked, nor subjected to any mental distress. You will see that I have no accurate information as to the degree to which the amblyopia had proceeded, nor excepting from what he remembered as to the exact state of his discs. Still the case fits very closely indeed with the facts with which we have been familiar in a hundred instances of so-called tobacco-amaurosis. I have seen many a patient affected in just the same way improve immediately and permanently on leaving off smoking. But here we are assured there had been no diminution whatever at any time. Let me say here that my patient was a man clearly fond of pictorial effect and he may have unconsciously exaggerated. It may have been that he did reduce his quantity or quality, it may have been that he indulged to very great excess before the outbreak, or that there was something in the German tobacco which he got which specially poisoned him. I incline, however, rather to the belief that we have here an instance of one drug efficiently counteracting the ill-influence of the other. The opium perhaps relaxed the set of blood-vessels which the tobacco had thrown into spasm. This suggestion is in keeping with what was noted after the champagne dinner.

I have known many cases in which the subjects of smoker's amblyopia recovered perfectly although they never left off smoking; and of those who had given it up for a time, I do not know that I ever once witnessed a relapse when the habit was, as it always is, resumed. It may be thought that such facts go against the belief that tobacco has anything to do with it, and that this is made almost a certainty by such a case as that which I have just related. For myself I do not think so. Show me parallel cases occurring in those who do not smoke. It is possible even that one or two of such might be produced, but they are infinitely rare; whilst in heavy smokers, this form of transitory amaurosis is an everyday occurrence. If cases were forthcoming in which there had been no smoking, my reasoning would be this—there is probably a form of nerve disorder, perhaps a passing neuritis, perhaps only a vascular ischæmia, which may be induced by exciting causes of the precise nature of which we know nothing, but concerning which it is still in the highest degree probable that something acts as the predisposing cause. No doubt there is idiosyncrasy in the furthest background; as a middle stage the long-continued habit of smoking, and lastly, some unrecognised influence,—some depression of nervous tissue perhaps,—which determines the attack. The final exciting cause may in some cases be important, and in many it may perhaps be absent, the tobacco being itself sufficient.

You will see that these conjectures open to us a very interesting chapter in reference to the influence of drugs in general, especially of those drugs which we give over long periods of time and of those which become, with many persons, articles of ordinary use quite independent of medical prescription. We do not know but what other articles of which the chief influence is upon the nervous system may after long continuance produce injurious results. We can by no means safely assume that because a nervine stimulant is borne with impunity, or even with apparent advantage, that therefore it is wholly innocuous. It may be that its use involves the risk of very peculiar and wholly unexpected disorders. In the light of this conjecture we ought to examine as to all that is possible in reference to the different kinds of wine, tea, coffee, hops, quinine, absinthe, chamomile, and many others. I shall ask you presently to observe the facts as to the connexion between arsenic and attacks of herpes zoster, facts which are, let me say, somewhat similar to those in reference to tobacco and attacks of amblyopia. Before proceeding to this subject, I wish to take an illustration from an article which comes into the diet category. The study of drugs is often sufficiently difficult, but that of diet is surrounded by peculiar fallacies. Especially we must remember that both in prescribing and in feeding combination is often everything. A thing which might have agreed well alone, may poison when taken with something else, or conversely, that which alone would certainly have disagreed, may go all right with its proper adjunct. If you put tannin with your tobacco, a man wholly unaccustomed to smoking may take a pipe with impunity. So also camphor counteracts the effect of tobacco, and belladonna prevents the headache from opium. Not only must we keep in mind, in all questions of diet, the possible influence of some unremembered combination, but we must bear in mind, that the state of the individual varies at different times. Most of our patients are marvellously unobservant in these matters, or, rather, observe in a hurry, miss out facts, and arrive often very confidently at most erroneous impressions. Sometimes, however, we chance upon an acute and careful witness as to his own health and the things which help or hurt him. When such is found, prize him and listen in patience to his narrative. I have told you in a former lecture how in respect to "egg poisoning" it is often unsuspected by the patient, and how also in some cases it is only in certain conditions of health and under certain circumstances that eggs do disagree. Now just the same is true of tea and coffee, they will agree under certain conditions, and not under others. The man to whom tea has appeared for years to be an essential of comfortable existence, may suddenly find himself compelled to abstain from it. It may be that slowly this beverage has itself induced a change in the state of the nervous system; but it may also be that some other change in diet has taken place, or perhaps that it is mere result of advance in age.

Royal Institution of Great Britain.—The ordinary lecture season will begin next week. Mr. R Stuart Poole is to give the first of two lectures, on the "Interest and Usefulness of the Study of Coins and Medals," on Tuesday, January 15. Professor Ernst Pauer will on Thursday, January 17, give the first of a course of six lectures on the "History and Development of the Music for the Pianoforte and its Predecessors." And on Saturday, January 19, Professor Henry Morley will give the first of six lectures on "Life and Literature under Charles Ist." The Friday evening meetings begin on the 18th inst., when Professor Tyndall will give a discourse on "Rainbows."

CHOOSING ONE'S FATHER.

By ALEXANDER HARVEY, M.D.,

Consulting Physician to the Aberdeen Royal Infirmary; Emeritus Professor of Materia Medica in the University of Aberdeen, &c.

I.—Choosing one or other of two possible Fathers; and being allowed by Law the Choice of Either.

II.—Choosing two Fathers; and being by Law allowed the Choice of Both.

Strange—nay absurd—these two headings may seem. On reading, however, the details which follow, it will be seen, it is hoped, that there is substantial warrant for them—for the designations given to the cases about to be brought into view—the one, a hypothetical, yet a possible case; the other, one of actual occurrence.

I. Choosing one or other of two possible Fathers.

A man dies—is cut off suddenly, in the prime of life and in the full vigour of his powers. He leaves a young widow who has borne him two or more children, the younger or youngest being—say, sixteen months old. Losing no time in unavailing regrets, this young widow straightway marries another man—marries him, we will suppose, within two days after the death of her former husband. By-and-by she bears a child; and this child is born within such time as that by the laws of nature it may be the offspring of either husband. She may herself be unable to *say* which of the two is its father—quite unable to *conjecture* even which is the father. Physiologically, it may be impossible to determine the question. On the side of the child, there may be nothing in the way of resemblance to either husband to indicate that it was begotten by the one rather than by the other. Moreover, the circumstance of its having the features, or some of the features of the first husband would not, we know, be decisive as to the paternity.

As to this, it is now known, and indeed it is an accepted fact in physiology, that, by reason of the very intimate, albeit indirect vascular connection which obtains between the child while in the womb and its mother, and of the interchange of materials, as well effete as nutrient, continually taking place between the two through that medium, the infant may impregnate or inoculate the mother with the peculiarities, normal and abnormal, of its father. And thus it may happen, and often does happen, that in the case of a woman twice married and fruitful by both husbands, the children of the *second* marriage may, in not a few particulars, as regards both physical conformation and mental capacity and disposition, resemble the mother's *first* husband, and bear unequivocal traces of him. Many examples of this general fact are now on record. Let one suffice:—One day a young woman, residing in Edinburgh, called on the late Sir James Simpson in order professionally to consult him. He had never seen her before. Much struck he was, and not a little perplexed, at seeing in her very marked traces of the negro. On inquiry made of her, Sir James learnt that her parents were both of them white people—Scotch in fact; but that her mother, now respectably married to a butcher in Edinburgh, who was her father, had the misfortune while yet unmarried, and a servant in a gentleman's family, to be seduced by a negro, then also a servant in that family, and to have a child by him—a mulatto.[1]

This case is adduced simply in illustration of the agency of the child while *in utero* on the subsequent reproductive powers of its mother, and of the influence which that child may thus exert on the children its mother may afterwards bear to a second husband. Beyond this, the case cited has no bearing on the question at issue. If taken indeed as bearing on a question of this sort, it would be decisive of the paternity. If in the case of this young woman, there had been a question whether she were the offspring of a black or a white father, the circumstance of her not being a mulatto, but having traces only (however well marked) of negro blood, would make it clear that she was the issue of the white.

To revert now to the hypothetical case in hand, and assuming that there are no grounds of any kind, physiological, domestic, or circumstantial, for determining the real paternity of the child thus born into the world, Blackstone rules, that "it is more than ordinarily legitimate," and that on coming to the years of discretion, it may choose which of the fathers it pleases.[2] How important to it this question of choice might be, one may readily imagine.

Whether, in a case otherwise so insoluble, if legally brought in question, and especially if involving the succession to a peerage or to some thousands of broad acres, our lawyers would be content to solve it by a rule as simple as that indicated by Blackstone, may well be doubted.

II. Choosing two Fathers; and being allowed by law the free choice, not of either but of both.

Some seven-and-twenty years ago, or thereabout, a case was before the Courts at Westminster, and was eventually carried to the House of Lords, which very fairly warrants this other heading. A gentleman, who believed himself childless, and had no relatives he knew of or cared for, bequeathed by Will a sum of over one hundred thousand pounds to the town he was born in—a town not a hundred miles distant from London—in order to the founding therein of an Institute for the promotion of Art, Science, and Literature.

The Will, however, was not allowed to go unchallenged. A female, who had always been regarded, and had regarded herself, as the child of her mother's second husband, and who as such had long ago come into the possession of a handsome fortune, now stepped into Court and affirmed that she was the lawful child of her mother's first husband. The testator was this first husband. He had been married to the claimant's mother; but just after, or shortly after or before the claimant's birth, he had been divorced from her—divorced in due form, yet not with all the requisite legal formalities.

This defect, or something arising out of it, was, I believe, what gave the claimant a *locus standi* in disputing the Will. It was, as I have said, because the testator believed himself childless and heirless that he devised his estate in the way he did; and peradventure, the expression in his Will of that belief as a guiding motive with him in the disposing of his estate, may, for aught I know, or can now remember, have given strength to her position. Be this as it might—apart from her—the testator had no relatives that he knew of; and had he died intestate, the Crown was understood to be *ultimus hæres*. As such, it watched the case in its progress through the several Courts into which from time to time it passed. As we have seen, the claimant had never before considered herself the testator's child, neither had her mother, nor any one else; and, on the presumption of her being the issue of her mother's second husband, she had already inherited an ample fortune. I have no recollection now of the pleadings in the several Courts, or of the decisions pronounced; it will suffice to state that the case passed on to the House of Lords, and that on behalf of the party intended by the Will to be benefited, the services of the late Lord Westbury—then Attorney-

[1] See a series of papers by the Author "On the *Fœtus in-Utero* as inoculating the Maternal with the peculiarities of the Paternal Organism; and on the influence thereby exerted by the Male on the constitution and the reproductive powers of the Female." *Edinburgh Medical Journal* for 1859-60; also an Essay, by him, on "*A Remarkable Effect of Cross-breeding.*" Blackwood & Sons. Ed., 1851.

[2] *Commentaries.* Book I. chap. viii.

General—were secured, with a retaining fee of eight hundred guineas.

Fortunately, or unfortunately, on the eve of its being called in the Lords, the case was settled by compromise, without the question of paternity being there raised and determined. The town thought it better to get something rather than run the risk of losing all. And so it came about that the claimant was allowed—whether by my Lords, or without their leave, I cannot say, but with the consent of the Crown—to take out of the estate, or rather, out of what now remained of it, as the child of the testator, a sum little short of twenty thousand pounds. The amount that eventually came to the town for the purposes of the Institute, dwindled down from about one hundred and five thousand pounds to twenty-five or thirty thousand.

Thus possible is it in law, or by the favour of law, or at least with the concurrence of law, not only to choose one's own father, but to choose and be allowed two, and to derive very substantial benefit from both.

In choosing and being allowed the choice of *this* father, ought not the claimant to have been called on to renounce the other, and in doing so to disgorge all that she got by him? Her not being required to do this fully justifies, I humbly think, the heading given to this singular case. Nay, ought she not, in honour and in justice, to have herself arranged beforehand that, in the event of her being allowed, whether formally or informally, to be the child of her mother's first husband, and as such to take out of his estate the amount she did, she would hand over to the heir or the heirs-at-law of her mother's second husband, whom once she considered her real father, what she derived from him?

In the account now given of this second case, I stand open to correction in respect of incidental and subordinate particulars; not however as regards the substance of it.

P.S.—I have submitted what is written above to the friendly perusal of an able barrister, who has written to me as follows:—"The subject is curious, and the interest of it by no means merely abstract. I find your first doctrine is still laid down for law by Blackstone's latest editor, but he observes that that great lawyer Hargrave has questioned it. Upon your second doctrine I have some doubt whether you have used technically correct language. I should understand that the child was born after a stage in the divorce proceedings, equivalent to what is now a divorce decree *nisi*, and before the stage which would correspond to a decree absolute. If this was so, the man and woman were still at that time husband and wife, according to the judgment of Lord Chancellor Cairns, in *Norman* v. *Villars*, in 2 Ex. D. 359; consequently the child was the daughter, legally, of that man, in accordance with the principle *pater est quem nuptiæ demonstrant*. In this there would be nothing inconsistent with the fact that the child obtained property as the supposed child of someone else. *E.g.*, if the second man gave her a legacy upon the ground of a mistaken belief that she was his daughter, her title to the legacy would be good, although the belief were proved to be mistaken, unless it were proved that the belief was produced by fraud on her part. This is the rule laid down by Lord Chancellor Cottenham in *Rishton* v. *Cobb*, 5 Myl. & Cr. 145. In such a case I do not think it could correctly be said the child would take the gift as the second man's daughter; she would take as the person named by him to take, the fact that he thought her his daughter being immaterial. I have one other criticism to make—would not the Crown be said to claim the property as *bona vacantia*, if it was a sum of money, and not to claim as *ultimus hæres?* since in England there is no heir of moveable property."

REPORTS OF

HOSPITAL PRACTICE IN MEDICINE AND SURGERY.

THE MIDDLESEX HOSPITAL.

THREE CASES OF DERMOID CYSTS IN UNUSUAL SITUATIONS.

(Under the care of Mr. HENRY MORRIS.)

Case 1.—*Dermoid Cyst in Floor of Mouth; treated by Excision of part of Cyst-wall, and plugging with Lint soaked in Iodine Liniment—Subsequently, Death from Cancer of the Œsophagus.*

(From notes by Mr. ROBERT S. BOWKER.)

THOMAS H., æt. 54, a labourer, was transferred in October, 1882, from Dr. Powell's ward to Mr. Morris, on account of a large soft swelling on the right side of his neck and cavity of the mouth. He had been admitted on the 4th of August, because of a difficulty in swallowing which began five months previously, and went on increasing. For a month prior to admission he had swallowed only fluids, as the deglutition of solid food caused pain in the throat and dorsal region of the spine, and the bolus quickly returned after appearing to lodge opposite the second piece of the sternum. There was an indurated enlarged gland just above the inner end of the left clavicle, and a second a little higher up, in front of the sterno-mastoid. Beneath the right body of the lower jaw was an elastic rounded swelling, which occupied the floor of the mouth and raised the tongue distinctly above the level of the upper edge of the teeth. A No. 14 œsophageal bougie was passed into the stomach, but met with an obstruction, easily overcome, however, about three inches from the cardiac end of the stomach. No. 18 bougie could not be made to pass this spot, which was 14½ inches from the margin of the teeth. The patient was emaciated, had never brought up blood, was rarely sick; had had syphilis fifteen years ago, and knew of no malignant disease in his family, which was a very large one, viz., five brothers and nineteen sisters; eight of whom are alive now.

Over twenty-five years ago, Mr. Campbell de Morgan had incised the sublingual cyst and let out a large quantity of creamy matter; but it soon refilled and subsequently burst spontaneously. It had been many years coming to its present size.

By October 6th, swallowing had become still more difficult, though No. 14 bougie could still be passed into the stomach. It appeared, however, that there was some obstruction about six or seven inches from the margin of the teeth, and it seemed probable that the large swelling, which filled his mouth and spread backwards to the root of the tongue, was causing some of the difficulty in deglutition. Mr. Morris accordingly incised the cyst through the mouth on October 19th, cutting out a piece of the mucous membrane and cyst-wall as large as a florin. At least from 18 to 20 ounces of a creamy yellow semi-liquid substance, containing innumerable solid masses, escaped. Its general appearance was like egg sauce with grains of sago or rice thickly sprinkled in it; it gave an alkaline reaction, and consisted largely of saline and fatty matter.

On introducing a finger into the cyst after it was emptied, it was found to extend downwards, a long way below the symphysis and lower border of the inferior maxilla, and backwards to the body of the hyoid bone (which the finger touched, except only for the cyst wall intervening) and to the angle of the lower jaw. The cavity was stuffed with lint, soaked in iodine liniment, and daily irrigated with Condy's fluid. The cyst-wall suppurated, granulations slowly formed, and the space

contracted. On Oct. 26th, at 6 p.m., the patient had a severe rigor, and his temperature went up to 104·4, but there was nothing in the state of the mouth to account for this. The next day he was feeling very well, and no further rigor or elevation of temperature occurred. By Nov. 9th, there was nothing more remaining than a broad sinus opening into the mouth near the frænum of the tongue.

Immediately, and for a long time (after the cyst was evacuated), his power of swallowing was improved, and he was altogether much comforted by the operation; but by degrees the cancer increased, and he died of asthenia on February 13th, 1883.

Dr. Fowler made an examination of his body next day and reported: "The tongue was normal; in the mid-line close to the frænum there was an opening, the size of a crow quill, leading into a cavity about as large as a hazel nut, the remains of a ranula which had been opened and stuffed."

There was a cancerous growth in the lower part of the œsophagus 3¼ long, completely encircling the tube and constricting it, though a No. 12 catheter passed easily through it. The lower end of this growth was within half an inch of the cardiac extremity of the stomach: it had invaded the bronchial glands, and was adherent to the left lung, but had not perforated into the lung tissue. The stomach was of normal size, and there were no secondary growths upon it. The glands in the root of the neck and behind the pancreas were infiltrated with cancer, and a cancerous nodule growing from behind the œsophagus on a level 2½ inches below the cricord cartilage displaced the tube to the left, considerably narrowed its calibre, and had caused ulceration of the mucous membrane at one spot. There were caseous and miliary granulations on each lung. The kidneys were granular and the spleen large, soft, and pale.

Case 2.—Dermoid Cyst containing Hair in the Floor of the Mouth—Removal through an Incision below the Jaw.

(From Notes taken by Mr. A. Kirby.)

Chas. A., æt. 23, a potman, was admitted on March 6, 1883. Two and a half years ago he first noticed a lump below the left border of the lower jaw. It was then the size of a walnut, but has been gradually and painlessly enlarging ever since. He has had no difficulty in swallowing. When a child he had an abscess under the chin, the scar of which remains.

He is a healthy-looking young man, his general health has always been good, and he knows of no cause for the recent increased growth of the swelling. There is nothing in his family history pointing to an hereditary tendency to cystic or other growth of any kind.

The left submaxillary triangle is the seat of a considerable swelling, the greatest prominence being at the apex of the space; above it is limited by the posterior two-thirds of the base of the jaw. The skin over it is quite uninvolved, and there is no enlarged gland in the vicinity.

On looking into the mouth, a slight swelling of the whole of the left side of the floor, extending further back than the angle of the jaw, is noticeable; and the tongue as it rests is higher on the left than the right side. When pressure is made on the swelling in the neck, the left side of the floor of the mouth and base of the tongue bulge upwards considerably. Fluctuation extends across the swelling, from the neck to the floor of the mouth. A little yellow fluid escaped on puncturing the swelling through the mouth.

March 7th.—An incision about 2 inches in length was made below and parallel to the base of the jaw down upon the cyst.

The submaxillary gland was covering a large portion of its surface, and the facial artery and vein crossed it obliquely. On holding these structures aside with retractors, the cyst immediately protruded through the wound, and was so loosely connected with the surrounding tissues, that a good part of the cyst-wall separated from them by simple traction and a few touches with the knife. The deeper part dipped beneath the posterior border of the mylohyoid muscle, and in that way reached the floor of the mouth and base of the tongue. The cyst had no connection with the sheath of the cervical vessels, and its firmest attachment was with the tissues beneath the mylohyoid.

The wall of the cyst was very thin; the contents were a clear yellow fluid, with small gritty particles, and from its inner surface a single long light-coloured hair was growing. It was not thickly studded with fine downy hairs, as dermoid cysts about the orbit sometimes are.

For the first three days after the operation the temperature was 101·6°–102°. On the third day there was difficulty of breathing and a constant hawking up of thick mucus, which collected about the palate and fauces; there was also very extensive œdema of the whole of the left side of the neck.

Six leeches, followed by hot lead lotion fomentations, gave him almost immediate relief.

The temperature went down the next day to 99·2°, two days after to 98°; the œdema entirely subsided in the course of nine days, and he left the hospital quite well on March 22nd.

Case 3.—Dermoid Cyst containing Bone on inner part of the Thigh.

(From Notes by the Dresser, Mr. T. D. White.)

Robt. W., æt. 10, a schoolboy, was admitted on February 3rd, 1883, with what looked very like a fatty tumour of the thigh. It was stated that rather more than a year before he had first noticed a swelling and pain just above the right knee. He was a well nourished and healthy-looking boy, with a lobulated moveable subcutaneous swelling on the inner side of the left thigh, just above the knee, about the size of a Tangerine orange.

The tumour was removed, through an incision 2½ inches long; it proved to be cystic, with semi-solid sebaceous contents, and some small fragments of bone. The walls were thin, and adhered firmly to the vastus internus and upper part of the quadriceps extensor muscle,

The wound was dressed with terebene and oil (1 in 6) on lint, and the limb fixed upon a back splint. He was discharged quite well on 27th February.

St. John Ambulance Association.—A Public Meeting to inaugurate the formation of a St. John's Ambulance Association Centre in Hamilton, Bermuda, was held on December 6. His Excellency the Governor presided, and after some opening remarks, introduced the speakers, Dr. Hudson, Sir Thomas Brassey, and Lady Brassey, who addressed the Meeting, explaining the object in view. Chief Justice Rees having moved a resolution to form a Centre, seconded by Vice-Admiral Sir J. E. Commerell, V.C., K.C.B., the Hon. W. H. Gosling then proposed as the Local Committee, three Members of the Legislative Council, three Members of the House of Assembly, the Rev. Mark James, and Dr. P. B. Tucker and Brigade-Surgeon Kidd, P.M.O., and Attorney-General Gray having also advocated the movement, the usual votes of thanks were tendered to Sir Thomas and Lady Brassey, Dr. Hudson, and His Excellency the Governor. A Meeting for a like purpose was also held, attended by Sir Thomas and Lady Brassey, Dr. Hudson, and the Chief Government Officials at Port of Spain, Trinidad, a short time previously, with a similar result.

Medical Times and Gazette.

SATURDAY, JANUARY 12, 1884.

During the past week the Societies have been very active. At the annual meeting of the Pathological Society which was held on Friday last, January 4th, the President delivered an address, an abstract of which we print in our report of the meeting. He gave a brief but interesting review of the history of the Pathological Society, and referred to the various changes that had taken place in the doctrines of inflammation during that period. The following officers and Council were elected for the present year, viz. :—President—John Whitaker Hulke, F.R.S. ; Vice-Presidents—William Henry Broadbent, M.D. ; * William Cayley, M. D. ; * George Johnson, M.D., F.R.S. ; Samuel Wilks, M.D., F.R.S. ; Sir William Bowman, Bart., F.R.S. ; John Croft ; Arthur Edward Durham ; * George Lawson ; Treasurer—* John Wood, F.R.S.—Honorary Secretaries—James Frederick Goodhart, M.D. ; * Henry Trentham Butlin ; Council—Robert Barnes, M.D. ; John Curnow, M.D. ; Frederick Akbar Mahomed, M.D. ; Joseph Frank Payne, M.D. ; George Vivian Poore, M.D. ; Frederick Thomas Roberts, M.D. ; * Seymour J. Sharkey, M.B. ; Reginald Southey, M.D. ; * Francis Charlewood Turner, M.D. ; * Samuel West, M.D. ; * Arthur E. J. Barker ; * Henry Hugh Clutton ; William Harrison Cripps ; Alban Henry G. Doran ; Alfred Pearce Gould ; Thomas Ridge Jones, M.D. ; John Langton ; R. Clement Lucas ; * Henry Morris ; Edward Nettleship. The gentlemen whose names are marked with an asterisk (*) were not on the council or did not hold the same office during the past year.

The subject of diseases of the pancreas, which Dr. Moore introduced with his three cases of pancreatic calculi, is one on which it will probably be admitted by all that our ignorance is more complete than on any other. The records of the Pathological Society are wonderfully barren in respect of affections of the pancreas. One reason for this is doubtless the great difficulty in determining on the post-mortem table whether the condition of the pancreas is normal or abnormal. The exact degree of hardness which must be considered to be beyond the limits of a healthy state is far from easy to agree upon ; and if we cannot recognise disease of the pancreas with the naked eye, it need cause no surprise that we know so little of the symptoms it produces during life. Everyone has met with cases of carcinoma of the head of the pancreas, but what do we know about syphilitic or tubercular diseases of the gland? The debate was mainly limited to cases of disease of the pancreas that had been observed in association with diabetes. Bourchardat, some years ago, laid considerable stress on this association, and Seegen found atrophy of the pancreas present in fifty per cent. of his fatal cases. Drs. Hale White, and Savage, made an interesting appendix to their former paper on holes in the brain by describing cases of the same affection in the liver, and pointing out the reasons for not considering the changes to be due to putrefaction. Dr. Samuel West detailed two interesting cases of fatal hæmoptysis dependent upon aneurysm of a branch of the pulmonary artery, and Mr. Jessett brought forward a case of multiple sarcoma of the bones of the cranium in a young child, of which not a few examples have been exhibited at the Society during the last few years.

On Monday evening, at the Medical Society, Mr. Brudenell Carter delivered the first of his Lettsomian Lectures on "Modern operations for Cataract" which appears in full in another column ; the 21st of January, and the 4th of February, being the dates fixed for the second and third lectures. The following syllabus of the series has been issued :—Lecture 1.—Interest of the Subject—Progress made in dealing with it—Unsatisfactory character of so-called "statistics"—The old "flap" extraction—its merits and dangers—v. Graefe's early examinations—Mooren's method—Schuft—v. Graefe's "modified linear extraction"—Pagenstecher's method—Corneal sections. General results. Lecture 2.—The "maturity" of cataract—How ascertained—Advantages of waiting for it—Compensating disadvantages—Varying conditions in which the lens way be found—State of the nucleus—of the cortex—Conditions which justify early operation. Methods of procedure. Lecture 3.—The accidents incidental to early operation—Risks of the preliminary iridectomy—of the ultimate extraction. The advantages and disadvantages of anæsthetics—Complications which may arise after the operation—Treatment. Summary and conclusions.

A very interesting discussion followed on the reading, before the Medical and Chirurgical Society, of a paper on the "Direct Treatment of Spinal Caries," by Mr. Treves. Believing that the gravity of spinal caries depends not so much upon any special pathological feature in the process as upon the depth at which the disease is situated, and its inaccessibility to the ordinary operative procedures applied elsewhere, Mr. Treves advocates cutting down through the loin, and so reaching the seat of the disease by a direct route. He claims that by means of such an operation the vertebræ can be readily examined, and that carious or necrosed bone can be removed, and that abscesses can be reached, evacuated, and drained while they are small, and before secondary disease or changes have occurred.

There was a full meeting, and a long debate followed. This debate may be easily summed up by saying that, with hardly an exception, the speakers were in favour of the proceeding for the treatment of abscess ; while they deprecated, for various reasons, operative interference with the carious bone. If necrosed bone were present, of course it might be removed ; but this, in the experience of all, was a rare occurrence. Mr. Treves, in his reply, gave a much-needed hint that the treatment by mechanical means might be carried too far, and that it was a mistake to think that rest alone would suffice to effect a cure in all cases.

Mr. Treves' first case was that of a young woman with urgent symptoms. He cut down through the loin, got into a large abscess cavity, came upon diseased vertebræ, and found in the centre of one of them a loose sequestrum. Such a condition belongs to the greatest of pathological rarities; unfortunately, the case was almost lost in the consideration of the important surgical proceeding, which formed the gist of the communication, although it alone was worthy of a separate mention, of careful record, and of close clinical study.

There was a large attendance both of members and of visitors on Wednesday evening, at the Epidemiological Society, to hear what Surgeon-General Hunter had to say on the cause or causes of the recent outbreak of cholera in Egypt. The paper will not appear in full until next week, and for the present our readers must be content with the brief abstract which is contained in our report of the meeting. His contention, that the disease has been endemic since 1865, and that it was roused into activity by insanitary conditions, and perhaps atmospheric influences, is one of paramount importance; but as the brief discussion that followed his paper showed, it will not be allowed to pass unchallenged. The proverbial differing of the doctors was most forcibly illustrated by that discussion, for whilst Dr. Hunter and others did not believe in the communicability of cholera, Dr. Murray and Professor de Chaumont considered that this had been established beyond all doubt; and whilst Mr. Scriven thought that Dr. Hunter's conclusions were in advance of his evidence, Sir Joseph Fayrer considered that he had amply proved his case. The adjourned discussion will take place on Wednesday, February 13th, at 8 p.m., and will, we have no doubt, prove of great interest.

The paper on the same subject, which Surgeon-General Hunter was advertised to read at the Medical Society, on the 14th instant, is postponed to March 3.

At the last meeting of the Société Française de Tempérance, Dr. Dujardin-Beaumetz read a communication on the "Treatment of Alcoholism by Strychnia" (rather a curious subject, by the way, for a mixed lay and medical audience), in which he noticed the recommendation made some time since by Dr. Luton, of Rheims, that strychnia, being now recognised as the appropriate medicinal agent for alcoholism, the Government should authorise its addition to alcoholic beverages, in order to guard against their ill effects. Dr. Dujardin-Beaumetz, however, demonstrated, as the result of his experimental investigations and of observations made on man, that, although strychnia may be advantageously used in combating the symptoms of intoxication and acute delirium caused by alcohol, it is powerless as regards the multiple alterations in different organs which are the results of the presence of alcohol in the different tissues of the economy. Strychnia, therefore, is only, at the very most, a therapeutical agent, capable of causing the disappearance or mitigation of some of the symptoms induced by the abuse of alcoholic drinks.

Dr. Somerville, of Galashiels, read a most sensible paper "On the proper Age for commencing School Life," at the Congress of the Educational Institute of Scotland, on Thursday week. He maintained that, for Scottish children generally, the age of seven was a better time for beginning education than five, which was the recognized age, or three, which those in authority were contending for. By forcing children prematurely into school, a good deal more of what was really valuable in man would be obliterated, than if they were encouraged for two or three years longer to grow as nature and natural instincts would have them. One hour a-day was quite enough for a child to be kept to lessons, but when an infant went to grant-aided schools, he must be three hours in school every day, and if he got religious instruction, that must be extra. In the case of a little girl, she must be kept in still longer to get sewing; and he was told that a little girl of five or six might be in school from nine in the morning till half-past three in the afternoon. That was perfectly monstrous, and if the object had been to ruin the health of the child, and to make it, in other respects, a poor useless creature, the means could not have been better adapted to the end. Their rigorous climate did not admit of young infants going day by day to school with impunity, during the winter especially. On the fine days he would say they ought not to go to school at all. Fine days were too precious for an infant to waste them in school; they should be spent out of doors. Dr. Somerville's contention did not meet with the unanimous assent of his hearers, more than one of whom asserted that it was better for the children to be at school than at home. But it is a sign of the times that even Scotland should begin to kick at the educational goad.

Mr. Collier, Deputy Coroner for the eastern division of the county of Middlesex, recently saw fit to hold an inquest on a child who had died of bronchitis, without having had, as he considered, proper medical attendance. The infant had, it appeared from the evidence, been taken a few days before to Guy's Hospital, where it was seen by a "Dr. Stevenson," one, we presume, of the resident officers, who on being informed of its death, did not hesitate to certify as to the cause. A local practitioner had been called in, and finding the child dead when he arrived, he very properly refused to give any certificate, but regardless of the fact that it had been so recently seen by a qualified medical man, reported the case to the coroner. Considering how prone the poor are to seek medical advice, solely to avoid "trouble" *i.e.*, an inquest, and when it is too late for any other use, we should have little fault to find with the conduct of the coroner or of the Bethnal Green practitioner; but this does not seem to have been the case, seeing that the child was taken to the hospital.

At the inquest, Mr. Collier declared that a medical man, who had seen a patient only once, had not been in attendance in the legal sense, that the certificate offered was in itself illegal, and had been illegally obtained. If this be the law, he is in duty bound to

institute proceedings against Dr. Stevenson; but setting aside the circumstances of this particular case, it is perfectly monstrous to lay it down as a general principle, that a man who has seen a patient only once during life is not competent to certify to the cause of death. A patient may be attacked with profuse hæmoptysis or hæmatemesis, with apoplexy or cardiac angina, and die within an hour, and yet not a shadow of doubt exist as to the cause. Nay, more, we think that a man would be justified in certifying to a death from profuse hæmoptysis in a phthisical patient, even if life were already extinct, since there is no form of foul play or violence, the detection of which is the aim of the coroner's enquiry, that could well simulate the appearances of such a death. In the case in question, we should think that the medical man who saw the child when alive was more competent to vouch for the existence of bronchitis than he who only saw it when dead, and did not make a post-mortem examination, but on whose evidence the coroner instructed the jury to give their verdict. With the action of the parents in obstructing the entrance of the jury, and so on, we have nothing to do.

"Curious rumours, worthy of more or less credence, are daily reaching us," says the *Overland Mail*, "from Egypt, and all, unfortunately, tend to show a condition of internal dissension and antagonism among State bodies and State officials. It is, perhaps, not difficult to understand why the late Conseil de Santé should have fallen into disrepute with the Ministers, but it is most difficult to conceive why on that account those Ministers should think fit to ignore certain recommendations that have been made to them. The work done during the late cholera epidemic by the twelve English surgeons whose services the Foreign Office placed at the disposal of the Egyptian Government, has been admitted on all sides to have been most valuable and praiseworthy; moreover, it was carried out under circumstances which required very special qualifications: tact, courage, energy, and power of organisation had to be combined with great industry and professional skill, for in many cases the introduction of sanitary reforms meant that the reformer should assume the power and position of a governor. The Conseil de Santé strongly recommended that the Order of the Medjidieh or Osmanieh should be bestowed upon these gentlemen; now it is generally reported that the Egyption Government are afraid to decorate any one recommended by the Conseil de Santé. If this be the case, it is a fact more curious than creditable, and were it not for the length of time that has elapsed since the recommendation was made, the report would be unworthy of notice. As it is we can only hope to hear it contradicted." It is to be hoped that the new Egyptian Ministry may have more courage than the old. But we suspect that if the majority of the twelve doctors had their say, they would beg the Pashas not to let so small a matter interfere with their peace of mind.

A demonstration of the micrococcus of osteo-myelitis was successfully made before the Verein für Innere Medicin in Berlin, on December 17th. The cultivated micro-organisms having been injected subcutaneously, and into the blood stream, of healthy animals, produced no result except in those cases where some injury had been inflicted on one of the bones. In these a definite osteo-myelitis was induced, from the purulent discharges of which the micrococci could be again demonstrated and cultivated.

As we briefly mentioned last week, the Statistical Report on the Health of the Navy for 1882 was issued (as usual) at the close of the year following. In the limits of this short notice, it will be sufficient to record that out of a total force of 43,475 officers and men, the deaths were 413, of which number 299 were due to disease and 114 to injury. The ratios were 6·87 per 1,000 for the former, and 2·62 for the latter, giving a total of 9·49 per 1,000, which is a decrease of 1·45 per 1,000 when compared with the preceding year. This result is a subject for congratulation, when it is remembered that the year under notice includes the returns for the war in Egypt, in which what is termed the irregular force, that is to say, the Marine Artillery and Light Infantry, took a somewhat prominent part in the land operations. It has to be noticed, that on the home station no less than 67 cases of enteric fever were recorded, of which number 29 occurred in the *Seaflower* training brig for boys, whilst laying at anchor in Dartmouth Harbour. It is surmised that two of the boys contracted the disease whilst on shore at Southsea, from which port the *Seaflower* sailed for Dartmouth, and its rapid spread is attributed to the fact that for nine days before the occurrence of the first case, exceptionally wet weather had made it necessary to keep the awnings almost constantly sloped; this had greatly interfered with the ventilation of the lower deck, which, in the *Seaflower*, depends greatly on free access of air through hatchways and windrails. So bad was the ventilation of the deck during the last three days preceding the outbreak, the surgeon in charge states, that several of the men complained of the smell at night, and headaches, and in some instances vomiting, resulted in the morning.

It would appear that the lowest sick rate during 1882 was on the South East Coast of America Station, and the highest on the China Station; at the latter, the medical officer in charge of the flag-ship considered it his duty to call attention to the doubtful character of the water supplied to Her Majesty's ships. The returns from the Mediterranean Station are much less favourable than those for the preceding year; this is, however, to be attributed, not so much to an epidemic of remittent fever at Malta as to the circumstance of that island having been constituted the base hospital for the navy, so to speak, during the Egyptian operations. The foregoing may be regarded as the salient items in the report for 1882; but before closing our remarks, we are compelled once more to deplore the results which must inevitably follow the suspension of the Contagious Diseases Acts; we are informed in the present volume, that this is the last time the tables relating to their working can be compiled in their present form, and all the reports recently

received from the places originally protected concur in their testimony as to the evil effects which have resulted from this wrong-headed piece of sensational legislation. The records of these diseases, in the next annual report published, will, unless we are greatly mistaken, astonish even those who are most prepared for unfavourable results.

During the academic year 1882–83, six hundred and seventy-two M.D. degrees were conferred in France. Not far from three-quarters of the whole number, or four hundred and sixty-five were conferred by the Paris faculty. Montpellier comes next with sixty-nine; then follow Bordeaux with forty-six, Lyons with forty-three, Nancy with twenty-one, and Lille with twenty.

We often hear the doctor's opinion of the herbalist, but it is a rarer occurrence to hear the herbalist's criticism of the doctor. A member of what we must confess may really claim to be the older profession, is awaiting his trial on the charge of administering a poisonous dose of lobelia, and causing thereby the death of one of his customers. To do him justice, the herbalist appears to have had no very definite idea of the nature of the drug he sold, nor of the advisability of moderating the dose according to the condition of the patient. At the inquest, Dr. Stevenson deposed that the deceased had probably taken as much as 28 grains of lobelia seeds, the effect of which, he stated, would much resemble that produced by swallowing a strong solution of tobacco. The herbalist did not agree to this, but when arrested declared that Dr. Stevenson knew nothing about it. He then went on to affirm that the medical science of this country is a fraud—"God made the world and supplied it with herbs for every complaint, but these fools of doctors don't know how to use them and they are enemies of mine because I do." The position of this poor herbalist, with his arrogant faith in himself, is very pathetic. His belief that there is in Nature a remedy for every disease is not unknown in the profession, but at any rate one of the first things that these "fools of doctors"—or at least the vast majority of them—learn, is to work with Nature and not against her.

Sir William Harcourt has recently addressed a letter to the Chairman of the Prisons' Commissioners, congratulating them on the highly satisfactory character of their report for the past year. He considers the progressive decrease in the death-rate of the prisons, which has now reached 7·8 per 1,000 of the prison population (showing a diminution of 2·2 per 1,000 on the mean death-rate of the last ten years, and which so lately as 1875 exceeded 14 per 1,000), to be a striking proof of the successful care which has been bestowed on the health of the prisoners; and he desires that his satisfaction may be expressed to the medical officers at these results of their efforts. "Considering that the class of persons who are placed under their care are generally those whom vice and crime have rendered unhealthy subjects, this death-rate (even taking into account the number of diseased prisoners released on the score of ill-health) must be regarded as singularly low It proves not only that the caretaking of the prisoners is satisfactory, but that the diet and discipline of the prisons are not unduly severe." We are glad to record this compliment of Sir William Harcourt's to the Medical Officers of Prisons—a body of men, whose self-denying and secluded labours are hardly sufficiently recognised by the profession and the public.

The most costly pharmaceutical preparation in the market at present, is, without doubt the ergotine, prepared by the manufacturing chemists Gehe & Co., of Dresden. It costs 200 marks a gramme, or more than 13 shillings a grain. That is about £4,550 a pound avoidupois—a price in comparison with which gold is "dirt cheap."

One of the prerequisites of satisfactory discussion is a definition of terms. People have often fallen out when they were really one at heart, and have often agreed when really at variance, because they attached different meanings to the terms they bandied about in debate. Dr. Septimus Gibbon, the Medical Officer of Health for the Holborn District, has determined that this shall not be the case, if he can help it, in the great discussion which is now agitating the metropolis as to the homes of the poor. No one henceforth shall have to ask, and ask in vain, "What is a 'rookery'?" or, "How do you define a 'slum'?" The origin of a "rookery"—Dr. Gibbon informs the *Times*, and through it the world—"is, that a house built for the use of one family is made to contain six or more families, who use the street-door passage, staircase, washhouse, water-closet, dust-bin, and other sanitary appliances in common; and in the vast majority of cases there is no deputy landlord or caretaker to see that these common and necessary appliances are kept in order and not abused. The consequence is that, under the influence of this practical communism, all tenemental houses soon degenerate into 'rookeries.' When several of the 'rookeries' are situated in close, blind, narrow courts and alleys—often *cul-de-sacs*—where they are withdrawn from the view of the general public, they constitute a 'slum.'" Dr. Gibbon's definition of "slum" brings back to one the lessons of childhood—So many families, one "rookery;" so many "rookeries," one "slum."

The *Gazette des Hôpitaux* states that in the estimate now before the Municipal Council, the expenses of the Paris hospitals and hospices for 1884, are set down at 20,233,000 frs., being 616,500 frs. higher than in 1883. In explanation of this increase, the reporter exhibits a a tabular view of the rise in the amounts and prices of the various articles of diet, and of some medicinal substances. From a detailed comparison of the years from 1865 to 1882, it is found that the population of these establishments has increased by 21 per cent., the expense of medicines by 55 per cent., and that of diet by 41 per cent. The reporter calls serious attention to the alarming increase of these figures.

Those who have read Prince Krapotkin's article on the Siberian prisons in the December number of the *Nineteenth Century* will not be surprised to hear that

the sanitary condition of these pest-houses has at last forced itself upon official attention. It is stated, in recent official medical reports, that in the prison at Tomsk, the building in which persons condemned to exile in Siberia are lodged prior to setting out in gangs on their eastward journey, there were treated during the year 1882 no fewer than 1,268 cases of typhus fever. A still larger number of prisoners suffered from attacks of dysentery and recurrent fever, while 1,311 others, mostly children, fell ill of diphtheria, small-pox, and measles. Generally speaking, every inmate of the prison suffered from one or other of the above-mentioned diseases, and many from more than one. The number of deaths was very considerable. These official statements give a singular support to Prince Krapotkin's indictment, and tend to the conviction that the terrible picture he has painted is no less accurate in its other painful details.

Professor Reichert, who for so many years held the Chair of Anatomy in Berlin, died after a short illness on December 21st, having retired from the professorial duties, in which he was succeeded by Professor Waldeyer, only a few months ago.

Several cases of adulteration of milk, by milk vendors, have lately come before the Metropolitan Magistrates, in which it would seem that a far too lenient view of the offence has been taken. In one instance 18 per cent. of water was detected, and the defendant offered the excuse that he was *short of milk*, and therefore added the water; it was also urged that he lived in a poor and thickly-populated neighbourhood. The magistrate *cautioned* the defendant, and fined him 10*s*., and 12*s*. 6*d*. costs. It is difficult to see that being short of milk is the least excuse for committing a fraud, or that the inhabitants of "poor and thickly-populated neighbourhoods," are less entitled to pure milk than others. In fact, the authorities ought to be particularly careful that the poor, who seldom have a superabundance of food, should be provided with pure milk. In another case, 25 per cent. of water had been added. In this instance the defence set up was, that the boy upset the milk and filled up his can from a horse-trough. The defendant thought that it was hard upon him that he should be held responsible. At the suggestion of the magistrate, the summons was withdrawn. If the vendors are not to be held responsible for the acts of their servants, we fear that the practice of milk adulteration will never be stamped out. It is one of the evils of sending out milk in small cans in the charge of boys and women, that adulteration can so easily be practised. There were other cases. In two, 35 per cent., in one, 30 per cent., and in another 25 per cent. of water was proved to be present, and the vendors asserted that they sold the milk in the condition in which they received it. Fines were imposed, but the magistrate advised the prosecutor, who appeared for the Greenwich Board of Works, to try and bring the offences home to men in a larger way of business. This advice may be very good, but we would urge the importance of taking every possible means to check this serious evil. If the vendors are treated with sufficient severity, they will soon find a way of obtaining pure milk; but we think it most probable that, in the majority of cases in which milk is found adulterated, the fault lies with the retail rather than with the wholesale dealer.

The conditions of the milk trade indeed are such that the temptation to adulteration is especially strong in poor neighbourhoods. In the better quarters, where the profits on the cream trade help to make up for the small returns on the sale of milk, the business is a very flourishing one, and large fashionable connections are sold for thousands of pounds. But in poorer parts the facilities and attractions of the trade are such that competition is very severe, and the temptation to adulterate is keenly felt. The milk business, in fact, has great advantages over other retail trades. Milk is an article in daily use; no stock of it has to be kept in hand, no elaborate manufacture is required, and only just enough is bought for daily requirements. There are two ways of purchasing milk—either by contract with farmers direct, who undertake to supply so many gallons of milk daily at prices varying from one shilling and eleven pence a gallon in the six months from October to April, to eighteen or nineteen pence a gallon in the summer six months, delivered at the London railway stations, from which it is fetched by the retail dealer; or else by contracts with wholesale dealers, who perhaps charge a halfpenny a gallon more, and deliver it at the door of the retailer. These wholesale men themselves have contracts with farmers in certain districts for all their milk, which is cooled artificially as soon as it comes from the cow, and is sent up to London twice daily. The quantities dealt with are enormous. One man near King's Cross receives and distributes some 2,000 barn gallons of milk in this way every day; he has a cheese factory in the Midlands, and when the supply is greater than the demand the surplus milk is sent there and converted into cheese.

LIVERPOOL MEDICAL INSTITUTION

Milk, as everyone knows, is retailed at fourpence and fivepence per quart. Cream is bought at two shillings and two-and-sixpence a quart, and sold at four shillings, four-and-sixpence, and five shillings. The price given for milk businesses varies with the locality, and the price per quart the milk is sold at. If there is much cream sold, that enhances the value of the business considerably. Their value may be reckoned roughly to be about £20 a barn gallon in a fourpenny business, and £30, £40, or £50 a barn gallon in a fivepenny. Thus, if a man retails 30 barn gallons a day at fourpence, his business may be worth £600; but on the other hand, it may be valueless, for his working expenses may swallow up all his profits. A fivepenny business of that size may be cheap at £1,000, if there is some cream with it. It will be gathered from the above facts, which have been supplied by one thoroughly conversant with the trade, that in poorer neighbourhoods the profit is not excessive and that the temptation to adulterate must be very strong. So long, indeed, as magistrates treat the offence so leniently, the temptation will exceed the fear of punishment. A systematic supervision of the milk supply, and a rigid prosecution and punishment of adulteration would no doubt ruin a large number of the smaller purveyors, but it is to be feared that that

must be one of the first conditions of a pure milk supply. The excellent effect of well-organised inspection in some provincial towns is a proof that with energy and perseverance the same could be secured in the metropolis.

Let not the unwary reader of titles be deceived. Mr. Swinburne's new poem, which appears in the *Fortnightly Review* under the heading "Post Mortem," is not concerned with any dissection other than that of the motives and character of the deceased. The author must be credited with genius for discovering a new mine of wealth in purely technical terms. What a glorious vista of future poems opens to view at once. "Amputation," "Antiseptics," "Resection," and scores of others might be instanced as probable names for future effusions. Very little ingenuity is required to sever these from their original restricted meanings, and to give them a permanent life interest in the literature of the future.

The appointment of a Professor of Pathology in the University of Cambridge will be made next May. The salary we understand will be £800 a year, and the Professor will not be allowed to engage in private practice. The University School of Medicine is now the second largest in England, having increased with amazing rapidity during the tast ten years. Intending candidates for the professorship should lose no time in preparing for the election, as the contest for so good a post is sure to be keen.

On Wednesday, November 28th last, the St. John's Ambulance Association held their inaugural meeting in Bombay. The chair was taken by Sir James Fergusson, Bart., the Governor of Bombay, and the movement has received the warm support of the leading citizens and all the medical men of the city. The association is to be congratulated upon the favourable reception of its endeavour to extend its sphere of activity and public usefulness.

A correspondent sends us the following:—"I passed a few days lately amidst the quiet stagnation of a secluded district in lively Devonshire. My head-quarters were by the sea, in a village which reckoned itself a town in the summer season, when visitors and lobsters abounded, and shrunk into a hamlet when the birds of passage had flown, and the lobster pots had been carried away by stormy seas. Scattered around 'Flinty Beach' were many little agricultural villages, slumbering in autumnal decay. But at the time of my visit vegetable decay was supplemented by animal sickness. Epidemic disease was raging everywhere! At 'Flinty-beach,' presided over by a local board, measles prevailed. In some villages where 'sanitation' was still a thing for bumpkins to jeer at, measles was supplemented by diphtheria. Disease and mortality naturally increased in proportion to the neglect of drainage and water supply, and these matters, of course, could not be remedied at a moment's notice. All that science could do was to cure the patients, if possible, and to prevent the spread of infection. The patients were well attended, but I was struck with the total neglect of all precautions to prevent the spread of the disease. At 'Flinty-beach' people sent their linen to the wash, utterly careless whether the clothes of the sick were mingled, washed, and mangled with those of the healthy or not; and housekeepers seemed supremely indifferent to the weekly bundle being brought home by a youngster with the spots of measles on his stupid face. Kind-hearted people lent books to cheer their sick neighbours, but no one dreamed of disinfecting the magazine or novel when it was returned. Penny readings brought together the families of the healthy and diseased, and the day and Sunday schools were opened as usual. The inhabitants did not believe in precautions, and certainly would have objected to pay one penny for the sake of 'upsetting' and 'new-fangled busybodies' who pretended to have faith in sanitation.

"Never did I hear mention of disinfectants. Some old lady would, indeed, sacrifice to science by refilling her bottle of smelling salts, or burning some brown paper to conceal a suspicious smell. I could not help wishing that health officers in small, out-of-the-way country places, should be encouraged to use the power they theoretically possess. Round about 'Flinty-beach' it seemed to me that medical inspectors might be scientific, if they liked, but they dared not incur the suspicion of being fussy. And yet interference becomes a positive duty at times. Why should not the necessity of using disinfectants be insisted upon? Of course, it may be asked, what disinfectants? It is perfectly clear that one chemical agent is not likely to act satisfactorily in all cases. Food, clothing books, bedroom utensils, and drains require different treatment, but the poor and uneducated cannot be expected to understand this. Even their betters are content to pin their faith upon an advertisement, and to believe in some patented disinfectant, which shall meet *all* requirements, just as Morrison's pills can cure all diseases. Few study disinfectants scientifically, and yet every chemist will sell you a nostrum in the shape of soap, liquid, or powder, warranted to purify a decaying universe, and his only warrant for his faith in what he dispenses is the rapidity of its sale. Yet, surely, the liquid that purifies the drain would play the mischief with the wash-tub, and the fumigation which would cleanse the book would scarcely sweeten the provisions in the larder? I have often thought it would be a step in the right direction if the Local Government Board would issue to the medical officers of health in lonely country districts a list of disinfectants adapted to varied needs. A circular might also be distributed when necessary, to guide people who preferred to shut the door on infection to opening it to admit the doctor." We believe that not very long ago the board did contemplate issuing some plain and simple directions, such as our correspondent recommends, and we hope that no fear of interference with the sale of "patented remedies" may prevent them from carrying out their contemplation.

"A Contented Consultant," writes to us as follows, on the subject of consultants' fees: "Whilst agreeing with you as to the importance of the subject broached by your corresponent "M. R. C. P." in your last issue, I cannot follow you in thinking that depletion of the younger consultants would do any good. The number of young consultants (so called) will, in my opinion, always be regulated by the number of hospital appointments. Very few men would make any serious endeavour to start in consulting practice in London unless already attached to a hospital, and I do not apprehend that there will ever be any considerable increase over the present numbers. I have never been able to understand why our leading men have not raised their fees as time went on and their experience became greater. There is a well-known tale about the great Dr. Radcliffe, which shows that his fee in consultation was five guineas; why should the heads of the profession charge less now than was formerly the case? But I am wandering from my point. I wish to protest against the idea that all the young men who start in practice as consultants, do so in the expectation of pecuniary success; I believe that it is their love of science which, in the first instance, prompts them to go in for hospital work; and then when they have married and set up a brass plate in a very correct (professionally speaking) neighbourhood, they find that money is more necessary to their happiness, if not their very existence, than they formerly believed. Hinc illæ lacrimæ! The remedy is simple. Let those who want to make money, avoid science; the public-house line is open to them, and is always remunerative; and let those who determine to stick to science look forward to other rewards than pecuniary ones." We publish several more letters on this subject in another column.

It is announced that the late Dr. Marion Sims has left a sparkling sketch, which will appear in the February number of *Harper's Magazine*. It is entitled "Lydia McKay and Col. Tarleton," and describes one of the most romantic episodes of the Revolution—the rescue of her imprisoned husband by the beautiful and talented Lydia.

SURGEON-GENERAL HUNTER ON THE CHOLERA IN EGYPT.

The problem which Dr. Hunter brought before the Epidemiological Society, on Wednesday evening, was rightly described by the President of the Society as one of national—it is indeed one of international—importance, and it is a satisfactory sign of the place which medical science is gaining in the public estimation, that in this one instance, at any rate, politicians should stand still until science has spoken. It is true that other events in Egypt have somewhat thrown into the shade the cholera epidemic, and the problems which it has brought up, and that there is more pressing need to stand on guard against the Mahdi than against any recurrence of last year's epidemic. The question which Dr. Hunter raises would indeed have bulked much more largely on the political horizon if the new difficulties of the Egyptian Government and of our own had not dwarfed it. For in the clash of arms, Science has more or less to follow the example of her sister Law, and hold her peace. Still the issues involved in this question of cholera are likely, unfortunately, to be of a much more lasting interest than any false prophet that for a moment holds the stage, and though a passing thing may exclude them from the politician's field of vision, Science, with her longer sight, cannot afford to take her eyes off them.

The evidence which Dr. Hunter brought forward in his able paper, to prove that cholera has been endemic in Egypt since the last recognised epidemic in 1865, divides itself under four heads. The first of these deals with the hygienic condition of the country, and the facts which Dr. Hunter communicated are such as to give rise to wonder that cholera ever ceases to be epidemic there. The second class of evidence, collected in a very few weeks, from a large number of medical authorities, all residing in Egypt and *independent of the Egyptian Government*—the latter a very important point—goes to prove that bowel disease, whether under the names of diarrhœa, cholerine, or cholera-nostras, has been very fatal and very prevalent in Egypt since 1865; and Dr. Hunter's main contention is, that under those comparatively innocent terms many cases of true Asiatic cholera lie hidden. The system of death registration in Egypt is admittedly very defective, but all the returns agree in bearing testimony to the extreme prevalence and fatality of bowel disease during the last twenty years. It is on this point—the identity of cholerine, choleriforme, and cholera-nostras with Asiatic cholera—that the discussion will necessarily turn when it is resumed at next month's meeting of the Epidemiological Society, but until Dr. Hunter's evidence can be leisurely studied it is impossible to decide whether he has successfully held his ground. The least satisfactory feature in the evidence is that it is evidence from memory, the most important records of the facts which Dr. Hunter wishes to establish having been burnt in the conflagration at Alexandria. Still, many of the names which Dr. Hunter advances as supporters of his view are those of unimpeachable witnesses. A most important part of this division of Dr. Hunter's argument is that in which he tries to show that the suggested importation of cholera from India was impossible. The facts alleged as to the fireman of the *Timor* utterly broke down on examination, for he did not arrive at Damietta until two days after the first cases of cholera appeared; and the theory that the disease was left in the country by the Indian Contingent in 1882, though held by such a great authority as Von Pettenkofer, of Munich, will hardly commend itself to those conversant with the habits of cholera. As to the other alleged channels of importation, "the nameless Bombay merchant and phantom ships," as Dr. Couvidon describes them, their most remarkable peculiarity is that no one ever saw them, and few affect to believe in them. It is in this part of his paper, the negative demonstration, that Dr. Hunter is especially strong.

The third class of evidence is that collected during the epidemic by some of the doctors sent out from England. Dr. Honman and Surgeon-Major McNally both state that their enquiries gave them very strong reason to believe that cholera had been prevalent in the

districts to which they were sent during the months preceding the outbreak at Damietta. It is true that Dr. de Castro, a physician of considerable repute, who was commissioned to report on the epidemic by the Italian Government, holds that the cases alleged to have been examples of Asiatic cholera could not have been such in reality, because they did not propagate themselves, and this view was re-asserted by Brigade Surgeon Scriven in the discussion that followed Dr. Hunter's paper. But it is a view from which Dr. Hunter himself expresses his unqualified dissent though it will no doubt be seized upon as one of the most important points for discussion. It will be probably contended that in asserting that cholerine and choleriforme are but cholera in disguise, Dr. Hunter is proving too much; and when he admits his belief that examples of cholera, under this guise, are not uncommon in the cities of Europe, and even in the British Isles it looks to those who have been brought up in the ordinary views of the English School of Medicine as though his argument more nearly approached a *reductio ad absurdum*.

On the fourth division of Dr. Hunter's evidence, that derived from meteorological statistics, we need not dwell. It is curious and interesting, and in a subsidiary degree is not without importance. The observations made by Dr. Kirker, of H. M. S. *Iris*, during the period preceding the outbreak at Damietta, present a remarkable agreement with those reported by Mr. Glaisher during three different English epidemics of cholera; and the Arabic name for the disease—"the yellow air"—shows that the coincidence of cholera epidemics with a most unusual state of the atmosphere has not been remarked only by trained observers. But the precise causal relationship of the two phenomena has yet to be determined. One other little piece of subsidiary evidence, which is perhaps more important as a testimony of the utter demoralisation of Egyptian officials than as a proof of Dr. Hunter's view, is to be found in the statement made by certain men in authority, "We all know," they said "that cholera has been constantly prevalent here generally following the cattle-plague, but we are ordered to say nothing about it." Little weight, however, can be attached to such an admission.

THE HOMES OF THE POOR.

In a recent article on the dwellings of the poor, we maintained that the grounds of the distress to which, for some reason or other, public attention has of late been more than usually given, were to be sought, not in any circumstances peculiar to the tenure of property in London, or even in England alone, but in causes of universal operation, and inseparable from our present state of society. We promised that we would endeavour to indicate some of the directions which attempts to alleviate the existing evils should take, and we hasten to redeem our promise. The great mass of the people under consideration may be roughly divided into three categories, viz.:—(1) the industrial, (2) the labouring, and (3) the vagabond classes. The first includes respectable men, whose wages enable them to pay, say, five shillings a-week, or more, for their lodgings, of decent and mostly sober habits, and capable of appreciating good sanitary surroundings. For the better accommodation of this class, an extension of agencies already in operation is amply sufficient; it is on behalf of the second class, the labouring poor, that some interference with the existing arrangements has become necessary. For everything that has been effected in the past has but served to aggravate their distress. Every time an unhealthy area is cleared, hundreds or thousands are driven to seek shelter elsewhere, for the improved dwellings which, perhaps not until after the lapse of some years, arise in the place of those demolished, are beyond their means, and are invariably taken possession of by a better class. It is to be feared that there is good grounds for the allegation that the Metropolitan Board of Works are guided in their acceptance of the schemes submitted to them by the sanitary authorities more by the eligibility of a site for the erection of warehouses, or the opportunity it affords of opening up better routes for traffic, than by the unhealthiness of the area itself; but whether that be so or not, the practical result is the same. Scarcely different are the consequences of the smaller operations carried out by the local authorities under the older Act (with which the name of Mr. Torrens is commonly associated, though in its passage through Parliament his original draft was sadly mutilated), for though the site is immediately re-covered with houses they, too, are of a better, *i.e.*, a more expensive kind, and their former occupants are driven to other equally overcrowded districts, or to create fresh ones, by the appropriation of dilapidated and decayed streets as tenement dwellings.

We do not deny that some good is effected by these clearances; fever nests are abolished, even if others are indirectly called into existence, and the rookeries of the last, or vagabond class, are in many cases broken up. This class, composed of tramps, roughs, thieves, and prostitutes of the lowest grade, who retire by day to their dens, whence they emerge at nightfall to prey on respectable citizens, would gladly remain where they are, concealed from the public gaze, and comparatively secure from the reach of the law. Physically and morally degraded, strangers to the commonest decencies of life, filthy, vicious, and destructive, they would quickly turn the freshest and fairest of model dwellings into an Augean stable, and the best thing that can be done for them, because the most unwelcome, is to chase them from place to place, and by dispersing them so far as is possible, to bring them more within the restraints of publicity and the reach of the officers of the law, at the same time lessening their power of corrupting by their example the boys and girls of the struggling but honest poor. Further than this we are not concerned with them.

The vast population constituting the labouring class earn a precarious livelihood by work requiring neither skill nor education. This class includes the thousands of porters and labourers who pick up employment, essentially casual, in the various markets, wharves, and docks, hangers-on at theatres, &c., ground labourers and the unskilled assistants in the building trades, costermongers, and street traders of all kinds. To these may be added the workers, male and female, employed

mostly in the so-called "sweating" system by others as poor as themselves, and differing only in being able to get contracts from tailors and outfitters, or in making chip or card boxes and the like, trades in which the keen competition arising out of the superabundance of labour gives the only chance in the struggle for existence to such as will take work at the lowest terms that they find can keep them from actual starvation.

Their earnings—for it is only the ground and bricklayers' labourers who can be said to have wages—never exceed eighteen or twenty shillings, and frequently not half that amount, per week; and the necessities of their employments require them to live in close proximity to their work. It is obvious that they cannot afford more than eighteenpence or half-a-crown weekly for rent; though it is a fact that they often have to pay more. And it is no less certain that with the present cost of land and materials in London, it is quite impossible to build houses of any description in which such rents shall yield the most moderate return. Whether the local authorities, public companies, or private individuals undertake to provide dwellings for the working classes, they must proceed on ordinary commercial principles, and obtain a clear dividend of 2½ to 5 per cent., according as the philanthropic or the commercial considerations predominate. If the local authorities obtained loans from the State, repayable from the rates, the cost would probably be greater than under other circumstances, from the more stringent conditions as regards materials and workmanship that Government inspectors would impose. Private charity, even after the example of George Peabody, would be powerless in the face of a yearly addition of 60,000 to the population of the metropolis, half of which at least belongs to the class in question. The only practicable resource appears to lie in the conversion of existing streets and blocks of houses into tenements, and the improvement of such as already exist; such conversion or improvement to be undertaken by the local authorities or by companies or individuals who, inspired by philanthropic rather than by merely commercial motives, will be satisfied with the smallest remunerative return. As it is, every improvement enforced by the sanitary authority recoils on the occupiers, the total sum expended by the owner being at once added to the year's rent. Such property is, as a rule, extremely profitable, the high rents exacted from honest tenants covering the losses accruing from the conduct of the unprincipled. Unlike the vagabond class, the labouring poor are not content with the existing state of their dwellings, but simply with the rent; and they dread the visit of the sanitary inspector as foreboding an addition to their already heavy burden. Besides which, the nature of their employments, in many cases, excludes these poor from existing model buildings, quite apart from the question of rent, for the habits and belongings of costermongers and the like, however respectable in their way, are incompatible with the regulations very properly enforced in such places, and gladly accepted by the more select class who people them. In these converted and improved tenements certain simple but necessary sanitary regulations and appliances should be insisted on. Cheap but efficient closets, with an adequate supply of water, should be provided. A separate constant service for drinking and domestic use, secure from wilful or accidental pollution, proper ventilation and interception of soil and waste pipes, should be insisted on, &c. As regards the dwellings themselves, a minimum space of 350 cubic feet for each adult should be enacted, and at the same time there might be some relaxation of the rule as regards the occupation of a single apartment by persons of different families if of the same sex, while indecent occupation of one room, even by members of the same family, should be strictly forbidden.

Doubts seem to be entertained by many as to the competency of local authorities to undertake such schemes, but there are Acts older than and not repealed by the Artisans' and Labourers' Dwellings Acts—viz., the Labouring Classes Lodging Houses Acts, 14 and 15 Vic. c. 34; 29 Vic. c. 30; and 30 and 31 Vic. c. 28—which give power to the authorities, with or without loans from the Public Works Loan Commissioners, to buy, lease, or otherwise acquire lands for the erection of such lodging houses, or to acquire any already existing, and to alter or improve the same, to frame bye-laws and regulations for their conduct and occupation, and, if they see fit, to sell or otherwise dispose of the property after seven years.

In one or other of these ways of rendering tenement dwellings healthy and decent, and at the same time of letting them at rents within the means of the labouring poor, lies the only solution, so far as we can see, of the problem how to provide better houses for the really poor. Questions affecting the labour market, emigration aided by the State, the extended substitution of factories, private co-operative or State-supported in place of sweating and other forms of home work, though of high interest to the social reformer, scarcely fall within our province to deal with.

THE DIRECT TREATMENT OF SPINAL CARIES.

Good service was rendered to the subject of spinal caries, by the gauntlet which Mr. Treves threw down a few evenings ago at the Medico-Chirurgical Society. "Rien n'est sacré pour un sapeur" is a saying which will shortly be applicable to our modern surgeon, in that there will soon be few regions of the body which will be safe from his prying eyes, and his all-invading knife and fingers.

Spinal caries has long been one of the most troublesome and least satisfactory of those diseases which the surgeon has to treat, not only on account of its great inaccessibility but also on account of the great extent over which it may and usually does spread. Moreover, the anatomical characters of the bones affected, viz., their sponginess and great vascularity, lend additional importance to any inflammatory process which may be set up. Expectation therefore ran high when the above paper was first announced, in which the direct treatment of spinal caries was to be advocated and backed up by the record of three cases in which the operation had been performed.

The outcome of the discussion, though of very great interest and importance, has not quite borne out what

the title of the paper first promised, viz., direct treatment of carious bone. But, as a means of examining the lumbar vertebræ, of reaching any possible necrosed and loose fragments of bone, and more especially as a means of opening, draining, and treating abscess of this region on the most approved principles, the operation promises to be of great service.

Mr. Savory, in his usual masterly style, pointed out all the dangers which would attend the *satisfactory* treatment of spinal caries, by referring to the difficulties and contrasting the treatment of tarsal caries, even since the use of Esmarch's bandage had so much facilitated this proceeding. Caries, said Mr. Savory, is not a primary condition, but is preceded by inflammatory changes; and, unless the whole of the diseased tissue could be removed, the operation might prove worse than useless. Moreover, there are other dangers which were not alluded to. In young persons, the subjects of this disease—mostly of a scrofulous or tubercular type—there is always the danger of setting up an acute tubercular process, which is rapidly fatal, either in the form of meningitis or of general tuberculosis. And lastly, the removal of carious bone will not always save life, even should the local mischief be cured, as one of the recorded cases proved.

Nevertheless, the proposed operation was carefully worked out on strictly anatomical lines, and its feasibility was demonstrated. For the removal of pus, it can hardly fail to be of the great service. The only difficulty will be to recognise pus early, and this is certainly not an easy matter. One of the speakers referred to the relative frequency of pus collections in disease of the lumbar and lumbar sacral regions, as compared with other regions of the spine, and this will, in a measure, justify an exploratory incision when the disease is situated low down and the presence of pus suspected. We shall probably not have to wait very long for further records of this operation, and can only hope that "the mania" for new operations, to which some speakers referred, will not outweigh that discretion which, in a surgeon especially, is even better than valour.

REVIEWS AND NOTICES OF BOOKS.

Dr. FOTHERGILL ON DIAGNOSIS.[1]

After perusing this last book of Dr. Fothergill's the reader will be struck with surprise at its modest dimensions, for the nature of its matter and style is such that it must have been difficult for the author to know where to stop. But exhaustion comes to every one soon or late, and Dr. Fothergill tells us, at the end, that he knows he has written voluminously, and that the time has arrived when he must take leave of his readers. His books have sold well, he further says, and brought him practice; but for the future he must confine himself to revising and enlarging the new editions their popularity demands. And then, to his many readers, as to one compact individual, he addresses the singular and final verb, *Vale!* Truly, if a mind of a somewhat inaccurate turn, a determination to create imaginary enemies for the sake of filling pages in writing them down, and a fearless indulgence in repetition, were enough to make a book a commercia success, Dr. Fothergill should have many imitators. But there is a still more valuable element than these in his method of composition, a talent which enables him to distance all rivals in his line. He has a ready pen, and to his graphic style it is not easy for many to attain. He may be said to have mastered the art of the appropriation of common-place, and to have overcome the obstacle which Horace recognised when he said—*Difficile est proprie communia dicere.* Much that he says, though but seldom new or requiring re-statement, is doubtless true; and occasionally he amuses us with his original way of putting things; but apart from these merits, this ultimate volume of Dr. Fothergill's "standard works" can claim but scanty praise.

The title of the book is grandiose enough, but it is sound and little more. In the author's interpretation of it, as gathered from the contents of the volume, it does not mean much, or rather it means too much, which comes to the same thing. The physiological factor in diagnosis is surely recognised, being almost synonymous with diagnosis itself. Are not all medical students taught physiology before practical medicine, and is not physiology indeed styled at the University of Edinburgh "the Institutes of Medicine"? But it is not unfair to say that, in Dr. Fothergill's present terminology, the physiological factor seems to stand for all methods of questioning and examining patients whatever, with the exception of the use of the stethoscope, which is apparently glorified with the exclusive appellation of the physical method.

With a magisterial air, which, if not so serious, would be almost humorous, Dr. Fothergill tells the general practitioner, whom he from time to time advises not to neglect consultation with a physician, that the use of the stethoscope is not the only method of finding out what is the matter with a patient, and that the detection of a murmur at the heart does not fully cover the investigation of heart disease. That the use of the stethoscope is the main theme of medical teaching in the metropolis, and that students are never told to examine the pulse or the tongue of their patients, seems to be a fixed idea in our author's mind. This misconception and obliviousness of the actual state of things, arising probably from his own want of connection with any medical school, may partly account for his frequent sneers at the teaching of others, and his apparent conviction that there is a higher doctrinal revelation vouchsafed to him than to those who are attached to teaching bodies. Having started with the notion that but little is taught or known about practical medicine, Dr. Fothergill proceeds easily to fill his book with a discursive account of many of the symptoms occurring in cases of derangement of the various systems of the body. The reader is treated to the very simplest fare in the way of instruction, and the frequently repeated recommendation of ordinary common sense and decent manner in dealing with patients seems very superfluous, except to a class of students whose failure to pass their examination at all would be a public benefit. In fact, Dr. Fothergill lays most stress on what is generally, with reason,

[1] The Physiological Factor in Diagnosis. By J. M. Fothergill M.D. Baillière, Tindall, and Cox, London. 8vo., pp. 253.

taken for granted: he has constantly glimpses of the obvious himself, and then gravely communicates them to his humble and trusting readers. We are not surprised to hear, for instance, that "All apex mischief is not recent when found by the doctor," and that instruments of precision come in more fittingly at the close of the examinations rather (*sic*) than at the beginning. Again, we are told that the grass-green colour of the stools of children is not always due to hydrocephalus, and in another place that prognosis rests on accurate diagnosis.

A certain tendency to run down the value of physical examination in the author's too obviously right efforts to preach that medicine should be taught as a whole, or by what he calls the "physiological" method, though especially repudiated by him, will, nevertheless, be charged against him by most who look at this book. It is not good for a student or a practitioner to be told how an amyloid liver was diagnosed by Dr. Fothergill by the mere application of the hand to the abdomen, and how a prescription for it was written at once, as an illustration of the value of previous experience. With the minimum of good in such teaching as this there is a maximum of harm: the good will be found out by individual experience; the harm will result in the substitution of mere glances and touches for systematic examination, and the parading of lucky "shots" as brilliant diagnoses. The style of this book though, as we have said, readable and graphic, is not by any means free from errors—the grammar is often slipshod, and in one page we chance on three instances of contempt of schools other than medical; for there is no justification for spelling *otoliths* as "*otolites*;" for writing the initial *o* in the Greek word for "ear" as *œ* (as appears in the word "*œthœmatoma*"); or for changing an *e* into an *i*, as in concatinatæ.

Surgical Applied Anatomy; by Fred. Treves, F.R.C.S. Cassell & Co.—The need for a good book in English upon Applied Anatomy has long been recognized, and it would have been difficult to have selected anyone better qualified than Mr. Treves to supply the want.

That a large number of students regard the study of anatomy as necessary drudgery is a trite fact; and it is impossible not to feel that this is in great measure due to the manner in which the subject is often taught—without any reference to its uses. But when the physiological ends attained by anatomical structures are pointed out, when it is shown that diagnosis by physical examination rests upon a knowledge of anatomy, and that this knowledge constitutes the basis of operative surgery, how much more attractive does this branch of the medical curriculum become? Mr. Treves' book is therefore very welcome as remedying the above defect, as far as surgery is concerned. Though intended chiefly for students preparing for their final examination in surgery, we think that it would be of great service to students in their first and second years, if read with the ordinary anatomical text-books. Whilst involving but little expenditure of time, this would show some, at least, of the uses of anatomy; would separate the important from the unimportant facts; and would invest the whole with an interest which would make "the dry bones live."

To all students, therefore, we recommend the book, feeling sure that it will yield not only knowledge, but pleasure. For it is very readably and thoughtfully written, suitably illustrated, and the chief points are impressed upon the mind by short references to striking cases.

Clinical Chemistry; by Charles Henry Ralfe, M.A., M.D. Cantab. Cassell & Co.—We have had the opportunity of examining another of the useful series of Manuals which is being published by Messrs. Cassell & Co.: the present is quite equal to its predecessors, and contains a large amount of useful information. The chief objection we should urge against it is its title, for many of the processes are of course necessarily such as could not possibly be carried out anywhere but in a well-appointed chemical laboratory, by well practised chemists, and belong rather to physiological than to clinical chemistry; written especially for practitioners, it contains all they can require, but also much more, which is a doubtful advantage. The two first chapters are devoted to a description of the organic and inorganic constituents of the body, with their chemical reactions. The following section is upon the Blood, Chyle, Lymph, and Milk. Two chapters are set apart for the Urinary and Digestive Secretions, and the final chapter deals with morbid products, such as Calculi, Dropsical and Hydatid fluids, products of degeneration, and certain morbid conditions such as Rickets, Scurvy, and Gout. As we should anticipate, it is especially the facts relating to the Urinary secretion that are most exhaustively treated, and, considering their practical importance, rightly so. The other chapters, however, are carefully thought out, and the book, having the advantage of a good index, will be found handy and useful.

ABSTRACTS AND EXTRACTS.

Antiseptics in Germany.—Dr. Lardy, on a visit to Germany, in a letter to the *Union Médicale* (December 27) furnishes some information with respect to the antiseptics now most in vogue in that country. The somewhat exorbitant prices of the Listerian dressings, and the search after a perfect antiseptic have, he says, not a little modified the practice of surgeons of late. The employment of spray is more and more abandoned, and is now only resorted to for the purpose of disinfecting the theatre before the operation. It is advantageously replaced by the frequent washing of the hands in a disinfecting solution, and by the more or less continuous irrigation of the wound and its vicinity by a 1 or 2 per cent. carbolic solution, solution of corrosive sublimate, &c., &c. The enthusiasm for carbolic acid has much abated, and in many universities its solution is only employed for the disinfecting of instruments, because it does not damage these. For other purposes that excellent disinfectant corrosive sublimate is preferred for its cheapness, and for the rapidity with which very weak solutions destroy the very spores of infecting organisms. The solutions most generally employed are 1 per 1,000 for infected wounds, 2 per 1,000 in ordinary cases, 1 per 5,000 for irrigation during the operation, and 1 per 10,000 in laparotomies, in which the object is direct injection of the peritoneal cavity. The results are excellent. In a certain proportion of cases some absorption of the agent is indicated by a slight elevation of temperature for two or three days at most, but this is very rare. The secretion of the wound is not abundant under the sublimate, and very good healing by first intention is obtained. The solution of this disinfectant has also the great advantage of not rendering the skin of the hands so rough as carbolic acid. *Chloride of zinc*, much recommended by Kocher, of Bern, also furnishes good results in a solution of 2 per 1,000, and is especially employed in washing out the peritoneal and pleural cavities, presenting as it does little danger of absorption. It is curious that Koch, of Berlin, should still deny its antiseptic value, for experience shows that he is absolutely wrong. More recently, Prof. Kocher has proposed the *subnitrate of bismuth*, the disinfecting power of which would seem to be more potent than that of iodoform, while it is exempt from the danger of the latter. For the irrigation of wounds a solution of 1 or 2 per 1,000. It may also be employed in powder, or a bismuth gauze of from 10 to 20 per cent. is easily made. Prof. Socin, of Bâle, has recently proposed *oxide of zinc*, which is preferable to bismuth only when more concentrated solutions are required. These two

last antiseptics are also employed in the form of a paste, in order to close in a hermetic fashion wounds recently sutured, and with bismuth used in this way splendid cicatrization by the first intention may be obtained. Last summer, a mixture of sugar and napthalin was used at the Strasburg Clinic, and Prof. Lücke, a great admirer of popular remedies, was full of enthusiasm for the new treatment. Iodine-water, thymol, and salicylic acid may be mentioned, although their employment has not become generalised: but, on the other hand, concentrated *tincture of iodine* has attained more and more favour as an energetic disinfectant in septic wounds, the cavities of abscesses and mortified and fetid soft parts. Iodoform is employed now more in France than in Germany, where fear of intoxication prevails. It is especially in favour, like napthalin, for small dressings at the dispensaries. For dressing wounds successive layers of bismuth paste are applied, which are covered by simple gauze that had been previously soaked for some hours or some days in a solution of carbolic acid, sublimate, or bismuth—squeezing out the liquid at the time of application. This gauze costs infinitely less than that of Lister and analogous gauzes, and furnishes quite as good results. The protective and caoutchouc have also fallen into desuetude, and the wadding is replaced by the most various materials. Nearly every clinic has its own procedure, from carbolised jute to turf, moss, sand, ashes, sawdust or powdered glass; marsh-turf, moss and sawdust are washed in abundance of water, dried and roasted at a temperature of from 100° to 100° C., and disinfected in a sublimate solution of 1 or 2 per cent. They are then dried, put into bags, and placed over the dressing in the same way as wadding.

Extra-peritoneal Peri-uterine Hæmatoma.—A recent number of the *Zeitschrift für Geburtshulfe und Gynäkologie* contains a long article bearing the above title, by Dr. A. Martin, of Berlin. This author believes that cases of the kind which the title denotes, present characters distinct enough for their separate identification. He describes four cases, in which the nature and exact seat of the disease were made certain by operative exploration. He quotes three other cases, in one of which the same diagnosis was established by operation, and in two by autopsy. From this basis, he gives the following as the characteristic features of this form of disease. First, the local signs. The uterus is very definitely displaced laterally, and generally pushed forwards as well. The tumour formed by the effusion is not in the middle line, but occupies one side only of the pelvis, so that on the opposite side the examining finger detects no abnormal signs. On examination per rectum, the lateral position of the tumour can be made out with precision, and when the posterior surface of the uterus is explored with the finger, it can be ascertained that the effusion is not situated between the uterus and rectum; in other words, that Douglas's pouch is empty. Next, the symptoms. The commencement of the illness is sudden, and marked by abdominal pain, hæmorrhage, and signs of collapse: but the symptoms characteristic of peritonitis—vomiting, distension of the belly, pyrexia—are absent. Believing that he has thus established the diagnostic signs and symptoms of this form of disease, Dr. Martin proceeds to apply his generalizations to other cases, in which the diagnosis has not been made clear by post-mortem examination, or operative exploration. He has collected from literature eleven such, and from these, together with the verified cases before mentioned, he proceeds to describe the etiology, pathogenesis, anatomy, symptomatology, differential diagnosis, prognosis, and treatment of the disease. It seems to us that all that our author has to say, that is at once important and novel, is based upon the cases in which the diagnosis was established beyond doubt: and therefore we refrain from further epitome. We may mention, however, that he regards the diagnosis between an old extra-peritoneal hæmatoma and a subserous fibroid, in the absence of a reliable history, to be quite impossible.

The Communication of Cancer by Contact.—We recently (*Medical Times and Gazette*, December 15, p. 684) quoted from a clinical lecture by Prof. Gaillard Thomas, the statement that repeated instances of cancer of the penis thus contracted are on record. In a note subsequently published, Dr. Thomas declares that in "the heat of a clinical lecture (!)" he had stated the matter far too strongly, for in point of fact he had not met with one case which he thought had so originated, and that he had not at his disposal evidence of such occurrence, either in his own practice or in that of others. Dr. Paul Mundé also, in a communication to the *New York Medical Journal*, October 27, states that never having met with such a case himself, he wrote to several obstetricians, as well as to Profs. Czerny and Billroth. None of his correspondents had met with cancer so communicated. Both Prof. Czerny and Dr. Mundé also refer to the fact that there is no instance on record of cancer of the finger having been contracted by either medical attendants or nurses from digital examinations of cancerous disease of the uterus.

Dropsy of the Amnios and Syphilitic Infection.—Dr. Dorland read a paper at the Canada Medical Association (*Canada Medical and Surgical Journal*, November), in which he narrates some cases, with the view of showing that when successive dropsies of the amnios take place, they are due to syphilitic infection, and may be warded off by submitting the mother to mercurial treatment during her next pregnancy.

Formula in Irregular Action of the Heart.—In a discussion on heart-disease at the Boston Society for Medical Improvement, Prof. Bowditch said that he had found the Galloway formula of great service in relieving even serious cardiac affections. Pulv. digital, gr. x; pulv. colchic. sem, gr. xx; sodæ bicarb., gr. xxx; m. and divide in pil. xx. One of these should be taken three or four times daily at first, reducing the number subsequently until one is taken at bedtime.—*New York Med. Record*, November 24.

Ligature of the Axillary Artery.—Dr. Fenwick, at the Medico-Chirurgical Society of Montreal (*Canada Medical and Surgical Journal*, November), related an interesting case of Traumatic Injury to the Axillary Artery after Fracture of the Surgical Neck of the Humerus, in which the above operation was successfully performed as an alternative to amputation at the shoulder joint, the conversion of a simple into a compound fracture being rendered less dangerous by fully carrying out antiseptic treatment. The radial pulse returned 45 hours after the ligature had been applied.

REPORTS OF SOCIETIES.

PATHOLOGICAL SOCIETY OF LONDON.

Friday, January 4, 1884.

J. W. Hulke, F.R.S., President, in the Chair.

Annual Meeting.

The Secretary (Mr. Henry Morris) read the report of the Council for the past year, which revealed a satisfactory state of affairs. The number of members had increased to 669. The death list of the past year included the names of Drs. G. H. Evans and C. Hilton Fagge, and Messrs. Nathaniel Montefiore, Jardine Murray, and Richard Phillips. Dr. Samuel Wilks had been made a trustee of the Society in place of the late Dr. Peacock. The Council referred to the debate on Diabetes which had been held during the past session, and to the report by the Committee specially appointed to examine microscopical sections of the brain and spinal cord in that disease. The Council referred with gratification to the prosperity of the Society financially, the expenses for the year having amounted to 560*l.* and the income to 626*l.* Reference was also made to the very great services rendered the Society by Mr. Wheatley. In conclusion, the report alluded to some recent changes that

had been introduced in the mode of conducting the meetings, and hinted that further steps would yet be taken in the same direction.

Mr. LAWSON proposed the adoption of the report. This was seconded by Mr. BARKER, and carried.

Dr. BURNEY YEO also proposed, and Mr. DURHAM seconded, a vote of thanks to the retiring members of Council; this was responded to by Mr. R. W. PARKER. Dr. SIDNEY COUPLAND proposed, and Mr. TREVES seconded, a vote of thanks to the other retiring officers, viz., Dr. GEORGE JOHNSON, F.R.S., and Mr. HENRY MORRIS, to which the latter gentleman briefly replied.

The PRESIDENT then said, that at the last Annual Meeting he had been unable to deliver an address, for the very good reason which he then gave. He thought the present time opportune to briefly review the career of the Pathological Society. Founded in 1849 with 93 original Members, its numbers soon increased to 130 at the end of the first year. From that time the numbers had grown almost steadily until the present, when they reached nearly 700. Of the original Members, 19 were surviving, including the first President, Dr. C. J. B. Williams. The "Honorary Members" were founded in 1847, the following being the original list, viz.: Andral, Cruveilhier, Vogel, Otto, Henle, Rokitansky, Allison, and Stokes; these had all long passed away, but by their works had left an abundant fruit to their successors. He (Mr. Hulke) had joined the Society thirty years previously, during the presidency of Mr. James Moncrieff Arnott, and he well recollected the interest with which he listened to the speeches of the older members. The original aim of the Society was more humble than at the present time, as shown in the following law: "That in the remarks made, in reference to specimens exhibited, all abstract points shall be as far as possible avoided." The original founders of the Society were practising physicians and surgeons, encouraged by the advances then being made in "General Anatomy," to seek to know more of the minute changes taking place in pathological processes. Therefore they rightly at first sought after facts only; but it was natural that, in course of time, they should go further than this. No one, having studied the clinical manifestations of inflammation, could help investigating its real nature and causes. The knowledge of the course and minute anatomy of cancers or fibrous tumours of necessity led to the desire to know what made the one malignant, the other innocent. The appearance, in 1858, of Virchow's Cellular Pathology, gave an impetus to the study of the cell as the starting point of pathological processes, which it had not attained to before. This was ultimately (in 1867) followed by the appointment of a committee on morbid growths, who were "to ascertain if any and what relation exists between anatomical structure, and those clinical features ordinarily regarded as malignant." This committee, as was well known, had now become a permanent committee of reference. About this time had sprung up the doctrine of diapedesis, *i.e.*, of the escape through the walls of the blood-vessels of the white blood corpuscles. He (Mr. Hulke) had always had some misgivings about entirely accepting this theory—one difficulty was the great obstacles which they (*i.e.*, the leucocytes) must sometimes encounter and surmount—another, the extraordinary change of property they sometimes underwent; he instanced, especially, erysipelas and suppuration occurring in the eyeball in the course of pyæmia. He thought that an admixture of the two modes of origin afforded the best explanation of the changes. Hueter's discovery of the *schizmoycetes* in pus corpuscles, afforded the best solution of the conversion of a leucocyte into a pus corpuscle. During the present decade had arisen a most important doctrine, admirably brought forward by Sir Joseph Lister, that inflammatory changes originated and were maintained under the influence of living agents, inseparably connected with the processes of putrefaction, a doctrine which had been tersely put by the late Professor Hueter, "without schizomycetes no sepsis, without sepsis no inflammation." Turning to plant life, he thought a rich mine was open to those who had the leisure to work it. Mr. Hulke in conclusion, alluded to some of the work done by committees of the Society, and spoke of the great store of well-observed facts contained in the Society's Transactions.

Dr. DUFFIN proposed, and Mr. LAWSON, seconded a vote of thanks to the President for his very interesting address. This was carried by acclamation, and the President briefly replied.

The result of the ballot for officers will be found in another part of the paper.

Three cases of Calculus of the Pancreatic Duct.

Dr. NORMAN MOORE described the above as follows:—1. A pancreas with a dilated duct containing numerous irregular calculi of carbonate of lime. The duct was most dilated near the head; there were stones in all parts of it, but it was nowhere completely closed. The patient was a man aged 40, who died of diabetes. The bile duct was pervious and there was never any jaundice. 2. A pancreas with its main duct slightly dilated and containing a calculus of irregular shape, around which there was a large abscess in the head of the gland. This abscess pressed upon the orifice of the bile duct sufficiently to produce great distension of the gall bladder. The patient was a man, æt. 43, who died in St. Bartholomew's Hospital from an attack of pleurisy following gouty symptoms. 3. A pancreas with great dilatation of the duct throughout its length. Near the orifice the duct was blocked by a small calculus of irregular shape. The whole gland was very hard, and to the naked eye showed a great increase of connective tissue. The papilla in the duodenum was enlarged, and the hardened tissue of the pancreas had constricted the bile duct so as to cause complete obstruction. The liver was of a deep green colour, intensely hard, with a general dilatation of its ducts, which everywhere contained watery bile, and bile gravel. The glands in the hilum of the liver showed no new growth, and a careful search showed none anywhere in the body. Sections of the pancreas under the microscope revealed an extensive increase of connective tissue, many bands of old growth traversed the gland, and there were patches of the nuclei of a more recent connective tissue growth. Some normal acini were visible, but most of the gland cells were more or less atrophied. No cells like those of the acini were to be found beyond their proper limits, nor were there any other signs of carcinomatous growth. The morbid change was of the same kind as that found in the liver of cirrhosis. Dr. Wickham Legg had shown that dilatation of the hepatic ducts produced an increase of connective tissue throughout the liver. In this pancreas a gradual dilatation of its ducts due to occlusion of its main duct by a calculus was probably the cause of the connective tissue growth throughout the gland. Cirrhosis of the pancreas as a result of calculus had not been described before. The patient was a man aged 64, who was admitted into St. Bartholomew's Hospital in July, 1883, and died in October. He had been ill for a month, and jaundiced for three days before his admission into the Hospital. The liver was not then enlarged, but on August 13th, was distinctly increased in size. During his illness the patient had many attacks of vomiting but no colic. The speaker had exhibited to the Society, in 1882, two cases

of abscess of the pancreas, the present was the only one which had been met with at the Hospital since then. In the three cases shown that evening there had been jaundice in only one, the last, and colic in none, but in all three attacks of vomiting were noticeable clinical features.

Dr. WILKS asked if Dr. Moore attributed the diabetes in his first patient to the pancreatic affection, and reminded the Society that at the commencement of the debate on diabetes, he had mentioned the subject which had since then been dealt with by Dr. Lancereaux in a separate treatise.

Dr. BURNEY YEO asked if disease of the pancreas had been suspected during life in any of the cases.

Mr. HENRY MORRIS had seen pancreatic calculi associated with calculi in the mesentery. Dr. Johnson had put together all the recorded cases in the Journal of Medical Sciences.

Dr. HADDEN had recently found a pancreatic calculus in a case of diabetes.

Dr. MAHOMED had twice found diabetes associated with pancreatic disease, one was a case of lipæmia, the blood clots being of a raspberry cream colour.

Dr. GOODHART mentioned a case of fatty degeneration of the pancreas which he had seen associated with diabetes.

Dr. HALE WHITE had examined the records at Guy's Hospital, and found that in three or four cases of diabetes it was stated that the pancreas was wasted or undergoing fatty degeneration.

THE PRESIDENT observed that the discussion had brought to light more facts in regard to the state of the pancreas in diabetes than the debate on that subject had succeeded in doing.

Dr. NORMAN MOORE, in reply, spoke of the difficulty about being certain post-mortem that the pancreas was diseased. The diagnosis was very difficult; perhaps repeated vomiting without evident cause was a sign of some value. He had not seen any case quite resembling what Mr. Morris had spoken of.

Medullary Sarcoma of Skull in a Child.

Mr. F. B. JESSETT exhibited this specimen, taken from the body of a child, æt. 9 months. A small lump had been noticed on the right temple one month before she came under observation; this had grown rapidly, and when the child was first seen was the size of a chestnut, somewhat tense and semi-elastic, the veins over it were very much enlarged. The child's father and his sister were the subjects of multiple lipomata. There was a history of phthisis on the mother's side. No history of any blow obtained. The tumour rapidly grew, and was punctured, but only bloody serum was obtained; a second tumour appeared and grew into the first, proptosis of the right eye gradually came on. Death, preceded by convulsions, took place five weeks from the onset. The tumour involved the parietal bone, and the temporal and malar bones, the zygoma and the roof of the orbit; a similar mass was found on the inner side of the left parietal bone, bound down by the dura mater, the right hemisphere of the brain was much compressed and showed a considerable depression. The tumour was soft, very vascular, reddish-purple, with fibrous bands passing though it. No secondary growths in brain or any of the viscera; the lymphatic glands were not affected. The only cerebral symptom during life had been frequent sighing. He believed the growth had started in the substance of the parietal bone, and grown outwardly and inwardly. The history of benign growths on the father's side was a point of great interest.

The President believed that many of these growths originated in the pia or dura mater, and spread thence to affect the bones of the skull. The exemption from cerebral symptoms was a fact with which everyone was familiar.

Mr. TREVES considered the case to be one of sarcoma commencing in the meninges.

Mr. LAWSON quoted a case from the Ophthalmic Reports, where an osteo-sarcoma caused proptosis, and led to the removal of the eye. After death the new growth was found to have invaded the cavity of the cranium far more than the orbit.

Cystic Degeneration of the Liver.

Dr. HALE WHITE read a Paper, communicated by himself and Dr. Savage, on the above subject. They reminded the Society that last year, when they showed specimens of the various forms of holes in the brain, there was one variety in which the change in the brain was part of a general formation of small cavities in the different organs of the body. It was urged at the time, in opposition to this view, that the holes were due to post-mortem decomposition, for in the liver a spongy condition from this cause was well known. Since the publication of that paper the authors had had brought under their notice the case of a woman suffering from acute mania, in whom a condition of liver was present similar to that described in the paper, on holes in the brain, and also a case in which the holes were clearly due to post-mortem changes. The differences to the naked eye were that in the liver affected by decomposition the holes were irregular, and contained gas which formed bubbles under the capsule, whilst in the genuine cystic degeneration the holes were regular and contained no bubbles. Under the microscope the difference was very marked, for in the latter case there was extreme vacuolation of the hepatic cells, one or more minute vacuoles appearing in the cell, gradually enlarging and pushing aside the protoplasm; soon the cell bursting adjacent vacuoles coalesced, and a large hole was formed. In the case due to post-mortem changes no such appearance was found. Under the microscope the vacuolated liver now shown was indistinguishable from that exhibited last year, when all the viscera were affected. Therefore, it was concluded that in those cases also the universal formation of small cavities was, as the authors then maintained, an ante- and not a post-mortem change. They thus came to the conclusion that this universal cystic degeneration, as a result of vacuolation, was a genuine, but hitherto unrecognised, condition which most commonly affected the liver, frequently only the liver and kidney, and, in rare cases, most of the viscera in the body.

Aneurysms of the Pulmonary Artery.

Dr. SAMUEL WEST described two cases. The first was that a labourer, æt. 40, who had suffered from a cough for twenty years; seven months before admission to the hospital he had had hæmoptysis, and three weeks before he had suffered from pain in the left mammary region, and had lost much flesh. For the last twelve days of his life he had brought up half-a-pint of blood each day. After death, the right lung was found to be emphysematous, the left was universally adherent. Its upper lobe contained a cavity as large as a Tangerine orange, in which there existed an oval aneurysm the size of a walnut. The aneurysm presented an irregular triangular rent, and was lined with laminated clot; it had contracted adhesions. The second case was that of a seaman, æt. 21, who had formerly been in the army. He had suffered from hæmoptysis and cough. On admission into the Victoria Park Hospital, phthisical disease of the right apex was discovered, with ulceration of both vocal cords. Hectic fever of well marked character persisted throughout his illness, although for a long period he continued to bring up large quantities of blood. It was estimated that he must have lost more than twenty pints of blood during the last few weeks of his life. After death the left lung was found adherent at the apex, but emphysematous elsewhere. A sinuous cavity existed in

the anterior part of the lower lobe. The right lung was adherent, the lower lobe collapsed, and a loculated empyema existed near the base. The aneurysm had ruptured by a small linear slit. Dr. West divided fatal cases of hæmoptysis according as the blood proceeded from the trachea and tronchi, or from the lungs. His cases belonged to the latter class, and the literature on the subject was meagre. Out of twenty cases Dr. West only once failed to find an ulcerated pulmonary vessel to account for the fatal hæmoptysis. Aneurysms of the pulmonary artery were generally small, not larger than a small cherry; rarely multiple, they occurred in the large branches of the arteries, in chronic cavities or their trabeculæ. There was no relation between the size of the cavity and the presence of an aneurysm. Their development was due to want of support of the vessels. They were not to be diagnosed till severe hæmorrhage had set in, they affected no particular age.

Mr F. Treves showed a man suffering from actinomycosis.

Mr. Heath showed a man with a recurrent tumour in the parotid region.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

Tuesday, January 8.

John Marshall, F.R.S., President, in the Chair.

On the Direct Treatment of Spinal Caries by Operation.

A Paper by Mr. Frederick Treves on the above subject was read and discussed. Mr. Treves contended that the gravity of spinal caries depends not so much upon any special pathological feature in the process as upon the depth at which the disease is situated, and its inaccessibility to the usual operative procedures applied to caries elsewhere. Diseased bone cannot be removed from the vertebral bodies, and the morbid products having to travel a great distance in order to be evacuated, are apt to induce immense purulent collections. These collections are usually opened at a point remote from the original seat of the disease. In the operation proposed by the author the anterior surfaces of the bodies of all the lumbar vertebræ and—with some reservation—of the last dorsal vertebra, can be reached from the loin. A vertical incision is made near the outer edge of the erector spinæ; the sheath of that muscle and the quadratus lumborum are cut through; the psoas muscle is incised and the vertebræ reached by continuing the operation along the deep aspect of that structure. The details of the procedure are fully described. By means of this operation the vertebræ can be readily examined, carious or necrosed bone can be removed, a ready and direct exit can be given to all morbid products; an abscess situated in the psoas muscle or in the lumbar region can be evacuated while it is yet small, and before it has led to a huge abscess cavity. If a large psoas or lumbar abscess exist it can be evacuated at its point of origin, and at a spot that, in the recumbent posture, corresponds to its most dependent part. If Hueter's statement be true, that the two vertebræ most frequently attacked by caries are the last dorsal and first lumbar, the operation should be capable of frequent application. The author details three cases in which he performed this operation. All the patients made a good recovery. In one of the instances he evacuated at its point of origin a psoas abscess containing forty ounces of pus, and removed from the body of the first lumbar vertebra a large sequestrum measuring one inch by half-an-inch. The immediate improvement in this patient's condition was very marked. In another case the psoas abscess had been opened in the thigh some months previously. By this operation a counter opening was made at the point of origin of the abscess from the lumbar spine, and the entire abscess cavity was drained by a tube passing from the origin of the psoas muscle to its insertion.

The President congratulated the author on his paper and invited discussion. He drew attention to the many specimens of vertebral caries which were on the table, and which he thought would help to decide the question as to the commonest position at which the disease occurred.

Mr. Treves somewhat amplified the details of the cases recorded in his paper: the young woman from whom the necrosed bone had been removed, was absolutely well; but the boy, though he had improved as to the local disease, had subsequently died of lung disease with amyloid degeneration of liver and spleen. The specimen of the diseased vertebræ was on the table, and showed the localised condition of the caries.

Mr. Barwell thought that Mr. Treves was to be congratulated, more especially on the closing paragraphs of his paper and on the very unusual condition found in his first case. He said the closing paragraphs, because in them would be found indicated that which will prove valuable in the operation described by Mr. Treves. He would occupy a few moments in considering the condition of bone in caries of the spine, as it was always, or very nearly always found. In a few instances there was a superficial caries occupying generally the front of the vertebræ, and usually spread over a good number of bones, over a far greater extent of surface than could possibly be reached during life. Such disease did not produce angular curvature, not, at all events, until very far advanced indeed. But the more common form was generally confined to three or four vertebræ—the upper and lower of the affected bones appearing to be only secondarily diseased by the corrosive action of pus—the middle bone when three, or the two middle ones when four vertebræ were involved, became carious, the front and lateral parts of the body quickly disappeared, so that there only remained a wedge of softened bone, infiltrated with and soaked in pus. To attempt the removal of such disease by operation, especially when that operation has to be carried out at a depth which precludes any very accurate guidance of instruments, must be fraught with such danger to the spinal canal that it would in most instances, if not in all, be unjustifiable; nevertheless, Mr. Treves was to be congratulated on his first case. On reaching the spine he had found an abscess cavity leading direct to a sequestrum, already loose, and, being pushed away by granulations, and it was easily removed. The patient of course was greatly benefited and got well. But such a condition about the spine was exceedingly rare, so rare that no operation could be founded upon it, more especially as it could not be diagnosed during life. Of the other two cases, one was a caries already healed, and the other a persistent one, both accompanied by abscess, and both benefited by free opening and draining away of the pus. It was on this point he thought that Mr. Treves' concluding remarks were valuable. Limited to its proper sphere, the operation would certainly take its place in surgery. This place was not the removal or gouging of carious parts of vertebræ, but the free opening, draining and keeping sweet of the abscesses which result from that disease.

Mr. Bryant congratulated Mr. Treves on having shown how the principles of surgery which obtained in the treatment of abscess elsewhere could be applied to the region of the spine; and although it must be felt that this plan would only prove of service in a few cases, the operation on that account was not to be depreciated. Contrary to the usual teaching, many abscesses in this region were not dependent on caries: or the caries when present was secondary to the pus, and not its source. The paper suggested a not difficult means of getting at pus in the region of the vertebræ during the early stage, and while the pus collection was small, and at a spot which allowed good drainage. It could, however, only be done in exceptional cases. The disease was not always in the vertebræ but almost as often in the intervertebral substance: in either case, however, the patients would be more likely to recover if the pus could be let out and the abscess cavity well drained. He would make just one criticism: he thought the drainage-tube was very much larger than it need be. Finally, he would say the idea was not altogether a new one; he had himself treated a few cases on this principle, though not quite after the plan now advocated by Mr. Treves.

Mr. KEETLEY said that, having found correct the statements made in Germany, as to the value of treatment by erosion and iodoform of caries of the bones of the limbs, he had been for some time anxious to discover a suitable case of caries of the lumbar spine on which to try the same treatment. But hitherto he had only met with two cases, which shewed little more than the practicability of such proceedings as those described by Mr. Treves. As however, they clearly proved this, he now mentioned them. In the first case, that of a girl of 16 with lumbar abscess, he opened the abscess and was able to discover a carious transverse process of the third right lumbar vertebra, as well as to examine the side of the body of that vertebra with the tip of his finger. With antiseptic drainage, and the injection of a solution of iodoform in ether, the abscess closed and the patient convalesced. In the second case, marked angular curvature had existed for many years in a woman now aged 29, and there were several fistulous openings about the loins, buttocks and thighs. These were scraped out, and the original seat of disease in the bodies of the lumbar vertebræ cut down upon by an incision similar to that described by Mr. Treves; but these bodies were found firmly anchylosed together, and, as far as could be made out, not at all carious. But caries was found on the dorsal aspect of the sacrum. This was scraped, and the wound and sinuses were injected with iodoform in ether. This patient is still in the West London Hospital, with wound and sinuses almost closed. The first-mentioned patient was operated upon on September 9th last, also in the West London.

Mr. NOBLE SMITH acknowledged the value of this suggestion: yet it was not a new plan, for Mr. Furneaux Jordan had advocated a similar plan some time ago, a fact, by the way, which in no way detracted from its merits. Mr. Jordan would only have had his plan applied in severe cases, which had resisted treatment for a long time. He (himself) thought that such an operation certainly ought not to be applied in early cases, and he made his modest protest against any such practice. In the recorded cases the operation had proved itself of value; but he thought that equally good results were to be obtained from rest. Many cases died because rest could not be effectually carried out.

Mr. MACNAMARA referred to the pathological differences in the cases, most of which were undoubtedly tubercular in character. Percival Pott in his admirable Treatise, had first drawn attention to this fact; he recorded how cases could be absolutely cured by counter irritative, a statement which his own experience would corroborate. The counter irritation consisted in the insertion of an issue in the back, which was allowed to remain *in situ* for two or three months or longer. Pathological anatomy had long since cleared up the nature of the disease, and shown its tubercular nature; that at first it is very local in its action and very limited, and that the diseased material, under favourable circumstances, is absorbed and replaced by new bone. Pott's cases were not all very early ones; for the Treatise was one on paralysis in association with spinal disease; hence probably the cases were far advanced.

Mr. KNIGHT TREVES (Margate) thought that the operation now advocated was suited to let out pus, rather than for the treatment of caries; and when pus was present, some such operation was clearly indicated. He had seen a great number of cases of spinal disease, and a more hopeless disease he could not conceive. The rarity with which the disease was seen in people of 30 or 40 years of age, was sufficiently accounted for by its mortality. As regards the removal of bone, he thought the proceeding a more doubtful one. It was difficult to diagnose necrosis of the spine; but such cases probably ran a more acute course, whereas caries was essentially slower, and more chronic in its course.

Mr. R. W. PARKER said all would sympathise with Mr. Treves in his wish to make spinal disease more accessible to surgical treatment; at the East London Children's Hospital he saw a large number of cases, and he was awake to the insufficiency of the present methods of treatment in a large proportion of these cases. An analysis of 183 cases of which he had notes, showed that the disease was located in the cervical region 9 times; in the dorsal region 82 times; in the dorso-lumbar region 21 times; and in the lumbar and lumbo-sacral region 37 times, while in 34 cases its exact locality was not specified. These figures did not quite agree with those of other observers as to the commonest seat of the disease. He could not agree with Mr. Treves in his view that the gravity of spinal caries depended not so much upon any special pathological feature in the process as upon the depth at which the disease was situated. His own experience was that abscess was comparatively infrequent in spinal caries. Thus, in the 9 cervical cases, suppuration was present in 2 cases; in the 82 dorsal cases, in 6 only; in the 21 dorso-lumbar cases, in 6; in the lumbar and lumbo-sacral cases, suppuration was present in 28 cases. He quite agreed with the last speaker, that the operation was chiefly suitable for the letting out of pus, rather than for the treatment of caries. Unfortunately it was by no means easy to diagnose pus. When caries was present it was desirable that healing should go on slowly, for in this way there was less probability of the nerves within the spinal column being interfered with.

MR. HULKE rather took exception to Mr. Parker's statistics; he had at first thought they referred to *post-mortem* examinations, but it was obvious on consideration that this was not the case, and indeed Mr. Parker had stated that the observations were made from a clinical standpoint. He would remind the Society that abscess in such cases only occurred late on in the disease, and that it was impossible to deny its existence even when it did not present on the surface.

MR. PARKER, in explanation, replied to Mr. Hulke, that he spoke from a clinical point of view. Many of the cases were under observation for long periods, and when recovery took place without the formation of an abscess, he had concluded that pus was not present in any considerable quantity. Moreover, he had made a few *post-mortem* examinations, and had been struck with the absence of pus; a small amount of thick caseous material was all that he found, in quantity quite disproportionate to the extent of the bone disease.

MR. HOWARD MARSH wished to criticise the title of Mr. Treves' paper, which ran thus:—"On the direct treatment of spinal caries by operation." Discussions which took place at that Society attracted attention in the profession, and he thought that many who read the paper might, unless a caution was given, be led to undertake operations, in cases of spinal disease, which would be attended by very unfavourable results. He believed, notwithstanding its title, the paper was intended by the author to advise the early treatment of spinal abscesses by free incision and drainage in favourable situations, rather than to recommend an operation for the removal of bone. On this understanding, he regarded the paper as one of great value. Such interference, he thought, would be attended with a very favourable result, in cases where otherwise recovery was unlikely. The paper, in fact, showed how the principle of evacuating matter early, so widely established in other cases, might be applied to the cases of spinal disease. But as to the treatment of the spinal disease itself, by the removal of diseased bone, he felt that to advocate such a step would be a great mistake. In disease of the spine, a sequestrum was very rarely present. The condition induced was that of caries: that is, the bone was soft, and in a state of molecular disintegration. But the line of demarcation between this and mere chronic inflammation could not be defined, and to cut away bone that was merely inflamed was mischievous; the mechanical injury did much harm, and bone was removed that would, if left, have recovered. He had seen, at the Hospital for Sick Children, many cases of large spinal abscesses, in which Mr. Treves' operation would have been very valuable. But he anticipated, notwithstanding the title of the paper, that the author did not wish to be understood as advocating operations on the spinal column, for the direct purpose of removing diseased bone; though, of course, should loose bone be found (as in the first case), it should be carefully taken away.

Mr. SAVORY said that he need hardly remark that any suggestion in surgery coming from Mr. Treves was worthy of most careful consideration, and perhaps the best contribution towards an answer to the question he had raised, would be given by pointing out some of the difficulties which

occurred to one's mind in relation to the practice he proposed. In the first place, then, it appeared that the operation could not, in most cases, afford an exposure of the diseased structures, adequate to enable the surgeon to remove safely and completely the carious bone. Even in situations far more favourable to operation, as in the instance of the tarsus, this difficulty not infrequently presented itself. Even here, everyone was grateful to Esmarch's bandage, for the clearer view it gave the surgeon of the condition of the several structures. What then must be the difficulty of cutting away carious bone in a satisfactory manner in the case of the vertebræ? And then again, for operations in caries to be successful, certain conditions are necessary. It is not every case of caries that is benefited by operation. The pathology of caries should not, in this question, be overlooked. The state called caries is not a primary one, and is preceded by changes of the nature of inflammation and disintegration; and unless the whole area of morbid changes can be included, an operation which deals with the surface of ulceration only may be worse than useless. The case of necrosis was quite different. If by an operation a sequestrum can be removed, then indeed the result may be very useful and brilliant. In fact, it is not too much to say that in such a case it may be the means of saving life. But then, how are we to diagnose the presence of a sequestrum? Seeing how many cases recover without operation, are we justified in commonly performing it on the chance of discovering a loose fragment of bone? He could not sit down without alluding to an observation which had fallen from Mr. Bryant, to the effect that psoas abscess not unfrequently occurred without any preceding disease of bone. If Mr. Bryant would record the facts on which this statement was founded, he would be doing good service to the Society and to surgery.

Mr. Eve, at the request of the President, had placed on the table specimens of spinal caries, involving especially the dorso-lumbar region. On looking through the catalogues of the Royal College of Surgeons Museum and St. Bartholomew's Hospital, he found that, roughly, in 60 specimens, the last dorsal or first lumbar vertebræ were involved in 30. but the latter in a minority of the specimens. Mr. Treves had stated in his paper that by the operation detailed the last dorsal vertebra could be reached, and therefore in a large number of cases the abscess could be opened at an early stage and drained by that method, although the bone disease might not be adequately dealt with. Mr. Eve was fully aware that Museum specimens did not offer an exact criterion of the actual proportion of cases of diseases affecting particular regions of the spine, but the above was an interesting fact which to some extent corroborated Hueter's statement.

Mr. Bryant explained, in answer to Mr. Savory's criticisms, that he referred to acute abscesses about the spine and psoas region. While pathologist at Guy's he had seen several cases of psoas abscess, not associated with spinal caries; further, he had seen cases of dried-up abscess within the psoas muscle and without caries. It was to such cases that he alluded.

The President remembered the case of a man who, after riding rough-shod over Hampstead Heath, received some injury, and shortly afterwards died of pyæmia. There was no external abscess, but an autopsy revealed a large suppurating hæmatoma within the sheath of the psoas muscle. The asserted greater frequency of disease between the last dorsal and first lumbar vertebræ was, perhaps, to be accounted for by the great mobility of the spine at this part. He then called on Mr. Treves to reply.

Mr. Savory explained that when he had referred to psoas abscess, he of course meant the ordinary chronic and not the acute traumatic variety.

Mr. Treves replied. He said:—Not only had the title of his paper been somewhat unfortunate, but the first of the recorded cases had, in a sense, been also a little in opposition to the object with which the paper was written. Many of the speakers had very reasonably surmised that the procedure was deliberately directed against the bone, and had for its principal purpose the removal of sequestra from the spine. He entirely agreed with all those who condemned such an object. He should be strongly opposed to the gouging away of carious bone from the spine and to the indiscriminate removal of the diseased parts. Sequestra were very rare indeed in cases of this kind, and in the first of his cases, the presence of the sequestrum, which he had removed, was entirely unexpected. The main purpose of the paper was to detail an operation, founded upon precise anatomical data, whereby, the lumbar vertebræ could be reached, and pus arising from bone disease be evacuated at its point of origin. The procedure merely aimed at placing disease in the spinal bones in as nearly as possible the same position with reference to treatment as caries of other parts. Mr. Barwell was opposed to the operation, because, as he rightly said, the exact site of the malady was not always certain. In answer to this he would ask which step was the more serious: A simple exploratory incision down to the spine under antiseptic precautions, or the leaving of a case of uncertain bone disease to quietly develop until it reached such proportions as to be readily recognised? Mr. Bryant's observation, that pus in contact with normal bone may in time lead to erosion of that bone, was very important, and was a strong argument in favour of evacuating a psoas abscess as early as possible. He was unable to see in what way Mr. Furneaux Jordan's proposed operation—mentioned by Mr. Noble Smith—resembled the one he had detailed this evening. He would agree with Mr. Smith that rest was of very great importance, but he believed that serious evils had followed a too great leaning towards that measure. It had led to the indiscriminate treatment of all spinal cases by apparatus. The apparatus appeared to have been considered all-sufficient. In many cases this treatment had fallen into unworthy hands. A large section of the laity still had the impression that all spinal maladies must be treated by apparatus of some kind. He did not think that the opening of a psoas abscess in the iliac region or just above the iliac crest was to be advised. The opening was some way distant from the seat of the disease, drainage was less easy and the operation less safe on the whole. He had found no difficulty in fully exposing the diseased part; tearing of muscle was not required. The bone was bared fully by the abscess, and when the finger was introduced into the abscess cavity the diseased district would be found to be as well exposed as by a dissection.

There was a large collection of specimens of spinal caries from the London Hospital, from University College, and from the College of Surgeons.

The Society then adjourned.

EPIDEMIOLOGICAL SOCIETY OF LONDON.

Wednesday, January 9th, 1884.

Norman Chevers, C.I.E., M.D., President, in the Chair.

The Cause of the Cholera in Egypt.

Surgeon-General Hunter said, that in regard to the recent outbreak of cholera in Egypt, there was one point in his report to the Government, which was of such paramount importance, that he wished to bring it before the members of the Society, and he intended to limit his remarks to that one point, viz., to inquiring into the origin of the commencement of the outbreak. Egypt, he said, was about the same size as Belgium, but with a population close upon 6,800,000 inhabitants, or 1¼ million more than Belgium. The soil was alluvial, rich in decomposing organic matter; the people were agricultural, and led an out-of-door life. The country was almost rainless, except for three months during the cold season, the sky was cloudless, the air dry, the winds almost always northerly. The Nile was the only source of water supply, and periodically inundated the country; the rise began in June, and attained its highest point in September, then gradually falling till the following June; the subsoil water level of course followed that of the Nile. The inhabitants mostly drank water unfiltered and before it had time to settle. At Cairo there was only one tank for drinking purposes, and

the water was highly charged with inorganic and organic impurities; in the fashionable quarter there was no attempt at filtration. The water supply at Alexandria was good, it was the only town in Egypt with a wholesome water supply. The Nile was polluted almost from its very source with filth, garbage, and the excreta of all the towns on its banks. At Cairo and Alexandria it was found to contain minute bacteroid organisms in considerable numbers. There had been greater pollution of the river than usual, by the carcases of animals that had died of typhus fever being thrown in, in order to avoid the fee payable on their death; thousands must thus have been thrown into the river. It had been rumoured, too, that the fellaheen had sometimes eaten the bodies of animals that had died of typhus. It was the custom of the country that all the domestic animals should live in the hut with the family. The cesspit system prevailed at Cairo, *i.e.*, holes were dug in the sand, but these were rarely cleaned or emptied, and the house pipes and cesspits were in direct communication. Some attempt at a sewerage system had been made in Alexandria, but the contents of the sewers were emptied on to the beach, and though the sewers were provided with ventilators, these had been closed five years before his visit. Moreover, the privies were in direct communication with the sewers. Throughout the country grossly insanitary conditions prevailed, but he was happy to be able to state that the *Conseil de Santé* had been abolished. The prevalence of bowel disorders was very marked, and he had no doubt that under the head of diarrhœa were included many deaths from cholera. As a rule, no attempt was made to register the cause of death until after the burial. In one town, out of 40 deaths 26 were due to diarrhœa; in another, out of 174, 93 were so caused, and at a later period in the same town, 57 out of 110. In Cairo, in 1882, out of 17,290 deaths, about 38 per cent. were due to some affection of the alimentary canal. In Bombay, in 1881, the mortality from bowel complaints was 2 per cent. Passing then to the events more immediately connected with the outbreak, he said that the campaign was very short; it took place away from the Delta, and the troops who came from India, and being picked were healthy, began to suffer from diarrhœa directly they got to Cairo. Since 1831 there had been five epidemics of cholera in Egypt, excluding the one in 1865. In his opinion, no country was ever more ripe for an outbreak of cholera than Egypt was. A commission, appointed immediately the news of the outbreak was given, decided that the disease was cholera, but could arrive at no conclusion as to its origin. Dr. Flood's theory of a stoker on board the *Timor* having brought it from India had been shown to be baseless, as the man was simply a drunken scoundrel, and did not arrive at Damietta until two days after the commencement of the epidemic. Ahmed Chaffey Bey and Salvator Ferrari had admitted, as the result of their investigation, that the insanitary state of Damietta afforded ample scope for the genesis of cholera. The other importation theories had also broken down: one was still under inquiry, viz., that the disease had been introduced by stokers and firemen plying between Bombay and Port Said, but he was confident that it had no foundation. He then referred to Dr. Couvidon's report, the substance of which was given in an article in these pages, and also to a communication in the pages of a medical contemporary, against the theory of importation. For himself, he did not believe in the specific nature of cholera, and regarded the recent epidemic as the outcome of a disease that had existed endemically in the country. He then referred to the evidence he had been able to collect of the existence of cholera before last June, mentioning the two children at the Greek School at Damietta, and quoting extracts of letters from Dr. Dutrieux, Sonsino, and Sierra, all of which were given in his second report, and have already been alluded to in these pages. Dr. de Castro had supplied some account of suspicious cases that he had seen from time to time, but he was of opinion that though they resembled Indian cholera, yet they were not cholera, because they were less grave, and because the cases did not spread. Dr. Mackay had done some good work in this direction. On the whole, he (Dr. Hunter) considered that he had ground for the belief that the disease had been endemic in Upper Egypt since 1865. He then briefly referred to the valuable aid he had received from the medical men sent out to assist him, especially from Surgeon-Major McNally, at Zagazig, and Mr. Honman, in the neighbourhood of Mehallet-el-Kebir, and quoted a speech made to Sir E. Baring by a high official: "We all know that cholera has been constantly here, and generally follows the cattle-plague, but we are told to say nothing about it." He had arrived at the opinion that cholera had been endemic in Egypt since the great epidemic in 1865, and his information had been received from medical men not in the employ of the Egyptian Government. It was no argument that the disease was not cholera, because its importation could not be traced, or because it did not spread. If the cases of cholerine were not true cholera, then cholera was not endemic in Bombay, for the cases presented no difference, either clinically or pathologically, from cholera. He believed that cholera was endemic in many towns in Europe and in the British Isles. Passing to the consideration of the atmospheric conditions, he referred to Glaisher's work in connection with the three epidemics in this country, and said that in India cholera had been associated with a high temperature and moist stagnant atmosphere. Dr. Kirker, R.N., had described how stagnancy of the air over one town had seemed to force the disease into existence, and had collated a series of charts for 13 years, from which it appeared that the weather of last June was exceptional, whilst that of the 9 or 10 days before the outbreak was unique in character. Dr. McDowell had dwelt upon the peculiar condition of the atmosphere, noting its yellowness, and the fact of the migration of the sparrows. The Arabic phrase for cholera meant—"the yellow air." He thought it was undoubted that there was some close relation between these atmospheric conditions and outbreaks of cholera, but whether of cause and effect or not, he was not prepared to say.

THE PRESIDENT thought they were all much indebted to Dr. Hunter for his instructive communication. It dealt solely with the question of the genesis of cholera—a question of national importance. For his part he was no believer in the propagation of cholera; and in India no precautions were taken with regard to the conveyance of the disease. Egypt and France at considerable expense and great inconvenience to others, did adopt such precautions.

SURGEON-GENERAL MURRAY said that Dr. Hunter's experience had well fitted him for the task which he had undertaken. There was no foundation for the theory that the disease had been imported from India. Dr. Hunter said that it arose spontaneously from insanitary conditions. What was meant by the term "spontaneous?" Did the disease suddenly spring into existence, or was there a gradual development, and if so, how long did it take? or was it called spontaneous because it could not be traced to any other source? The history of the disease displayed a dormant state, it might assume an active form in a few minutes, hours, days, weeks, months, or even years. He referred to an outbreak at Agra, where it was taken in the wards of the hospital by himself and others in a few minutes. The disease did not often remain dormant in a person more than 3 to 4 days. It was often communicated through the ground,

as in the case of a healthy regiment following an infected one on a camping ground. Coolies had been known to contract cholera in a very short time from opening graves from 6 to 8 years old. In Bengal there was not a single district that had been free from cholera for the space of one year. An endemic disease, he considered, depended on the locality, those living there would get it and might take it away with them, but they would not give it to any one elsewhere, it was a non-contagious disease. The communicability of cholera had been proved beyond doubt by two epidemics. In Hurdwar, in 1867, it broke out among some pilgrims who dispersed over the country and it broke out wherever they went, amongst the inhabitants of the district. Dr. Bryden had endeavoured to account for this by saying that an epidemic of cholera was then due. But in 1879 there was another pilgrimage to Hurdwar, and again it was spread all over the country following the track of the pilgrims, but this time, owing to the introduction of the railways, it spread much more rapidly, appearing in Mooltan two months sooner than on the previous occasion.

Brigade-Surgeon Scriven was not strong in the belief that cholera did not originate spontaneously, but he was not convinced by the evidence adduced by Dr. Hunter, that the earlier cases had been instances of true cholera; sufficient details had not been given to satisfy him. If the disease did not spread under such insanitary conditions, the disease could not be cholera. It was possible that hereafter he might be convinced that cholera had been endemic in Egypt, but there was not as yet sufficient evidence. The symptoms of true Asiatic cholera were suppression of urine, marked fall of temperature in the second stage, watery diarrhœa, vomiting, and a tendency of the disease to spread.

Sir Joseph Fayrer considered the paper of great importance, and a decided step in the right direction. He thought that Dr. Hunter had amply proved that cholera had been endemic in Egypt. He was sorry to see that the Egyptian authorities had recently imposed a fresh quarantine of 14 days on vessels from Bombay. He hoped that this paper would put a stop to these absurdities.

Prof. de Chaumont considered this a very valuable paper. Pettenkofer had distinctly asserted that our troops, during the late campaign, had brought the cholera from India; no cases were brought, but the troops had brought the disease to Egypt, and left it there. According to this theory, the disease was not communicated from one to another, through the vomit or fæces, but rather as a germ or ferment, which could flourish when it found a suitable soil. He agreed with Dr. Murray, as to the communicability of cholera, and did not believe in its spontaneous origin. In Egypt, the theory of the importation had not been proved. He considered that Pettenkofer's was the most plausible hypothesis; if this would not hold, then the germs of the disease had lain dormant for many years. There was in this country evidence of that kind, in regard to enteric fever, which could certainly lie dormant for a while.

On the suggestion of the President, it was agreed to postpone the further discussion of the paper until the next meeting of the Society.

ODONTOLOGICAL SOCIETY OF GREAT BRITAIN.

December 5th, 1883.

Joseph Walker, M.D., President, in the Chair.

Absorption of Hard Palate from Pressure.

Mr. J. B. Sutton showed a remarkable case of absorption of the hard palate, &c., as the result of long-continued pressure. The patient had suffered from perforation of the hard palate, of syphilitic origin, and for many years before his death he had been in the habit of closing the aperture with rags, increasing the size of the plug as the opening became larger, until the following state of things resulted. The anterior three-fourths of the hard palate, with the whole of the alveolar arch and teeth, had entirely disappeared; the antra, nasal fossæ, and mouth formed one large cavity, bounded laterally by the thin outer shell of the superior maxillæ, and above by the orbital plates of the maxillæ, the superior and middle turbinate bones and the cribriform plate; the nasal septum was almost completely destroyed, and the left lacrimal bone had disappeared.

Relations between Dental Lesions and Diseases of the Eye.

Some other interesting specimens having been exhibited, the discussion of Mr. Henry Power's paper on "The Relations between Dental Lesions and Diseases of the Eye," read at the previous meeting, was resumed.

Mr. Macnamara spoke highly of the value of the paper, which he believed to be the most complete collection of facts bearing upon this important subject which had yet appeared in the English language. Cases were not unfrequently met with in which atrophy of the optic nerve on one side occurred without any apparent cause—no local inflammation and no evidence of any central lesion. These cases were very puzzling to ophthalmic surgeons; in future he should always carefully examine the teeth. If it should be found possible to arrest these cases of amaurosis by extracting a few teeth it would be a most important discovery, and he thanked the author of the paper for calling his attention to this possible cause.

Mr. S. C. Gibbons, of Brighton, mentioned the case of a young lady who, after suffering for eighteen months from greatly impaired vision, said to be due to amaurosis, applied to him and had a number of dead and decayed teeth extracted. Improvement in the sight took place at once, and in the course of a few weeks it was almost as good as ever; one eye, however, remaining a little weak.

Mr. Smith Turner thought the subject of the paper concerned the ophthalmic rather than the dental surgeon. The latter might assist the oculist by pointing out sources of dental irritation which might escape the notice of his colleague, and would of course have the chief share in carrying out the treatment thus indicated; but, as the diagnosis and treatment of diseases of the eye required special knowledge and experience, it was evident that such cases as those referred to in the paper must be dealt with mainly by the oculist.

Mr. Savory remarked that Mr. Power's paper called attention to a most important principle which was constantly in action in all parts of the body, both in health and disease, viz., that intimate connection between different, and often distant, organs which was commonly referred to under the name of *sympathy*. The fact that the cause of disease might be in one part of the body and the signs of it in another, was one which should be constantly kept in mind, though it was, unfortunately, constantly forgotten.

Mr. Chas. Tomes said it had generally been thought that remote nervous disturbance was most likely to occur when the living tooth pulp was irritated. But he found that in most of Mr. Power's cases the teeth were dead; consequently the source of irritation was external to them and must have acted directly on the trunk of the dental nerve, which lay in close proximity to the roots of the teeth, and not upon its terminal filaments. He thought this was an important point and worthy of attention.

The discussion was continued by Messrs. Hunt, S. J. Hutchinson, Storer Bennett, and others, after which Mr. Power replied, and the President adjourned the meeting.

GENERAL CORRESPONDENCE.

THE PLETHORA OF CONSULTANTS.

[To the Editor of the Medical Times.]

Sir,—Will you allow me, as one of the younger London consultants, to express my views shortly on the subject of the social status of the profession and the fees of physicians, referred to in your last issue. I think the writer in the American journal has certainly missed the point when he states that the low social position of the profession is marked by a want of State distinction, and caused by the lowness of medical fees. The medical men who have done the State some official service are generally "honoured" enough, if titles be considered honourable; and it is not usual in other professions for the State to confer distinction on those who are simply successful or respected in their own sphere of work. When I read Dr. Clifford Albutt's admirable address

at Leeds, last October, I hoped that he had spoken the last word to thinking and self-respecting men on the subject of medical honours. The honours given at present to medical men are certainly no unfailing test of their real worth or of their social status; for we often find that really scientific men, whom the profession delight to honour, apart from their professional success, are by no means the first to receive titles, while many are decorated simply because they have been lucky enough to please the public, to make large practices, or to be the attendants on royalty or influential public men. With respect to the large number of consultants who are confessedly not doing any practice worth speaking of, it seems obvious that they must be left to take care of themselves. If they fail in making incomes, and are disappointed in consequence, they have themselves to thank for it, for they enter the lists with their eyes open. Many of them are satisfied with the position they acquire as hospital physicians and surgeons, and the opportunity they have of gratifying their tastes, and of doing scientific work; and certainly a large number do not begin their career with any strong desire or definite hope of making a large pecuniary success.

I admit that the profession, as a whole, is insufficiently paid, and am quite in accord with those who believe that this state of things is to be remedied by the raising of the fees of those who have made a recognised success and wide reputation. No one would lose if a dozen of our leading men would refuse to see a patient for the first time for a fee of less than five guineas, or even more, and who would ask at least three guineas a visit for any attendances, however often, at a patient's own home in London, should the patient desire them to undertake the case. By this means the younger consultants could fairly raise their fees, and the remuneration of the whole profession, including of course the general practiotioners, would tend to be improved. How all this, however, would assist in bettering our social status it is difficult to see. I am rather of the opinion that that happy consummation will come to pass when better educated men join the profession, of which we have ample signs at present, and good hopes for the future, and when the spirit of the tradesman comes to be gradually extinguished by a growing devotion to science and a wide love of humanity.

Yours, &c.,

A HOSPITAL PHYSICIAN.

P.S.—The suggestion of your correspondent, M.R.C.P., as to a *descending* scale of fees for (1) "Senior Physicians and Surgeons of Hospital Staffs;" (2) "Physicians and Surgeons of established reputation;" and (3) "Junior Physicians and Surgeons," is surely a very subtle joke.

[To the Editor of the Medical Times.]

SIR,—The day has quite passed for the mere aspirant to consulting practice to attempt it without very good reasons for his presumption. We fear that talent alone is hardly sufficient, but it must be helped by means from some source; the hideous "waiting" without it, is too great a strain now, when the absolute acquisition of the facts themselves whereon to base one's knowledge for practice, engross so much attention.

The smart young house-surgeon, or demonstrator, is often dazzled by the success of some fortunate junior member of the staff who has that greatest gift of all, the knack of "getting on;" he tries it, the result is rarely satisfactory, and if it be, is often a questionable imitation of a questionable method. Pure science slowly leads to practice, and should it ultimately do so, that very art of dealing with patients is placed in the background, or never has its chance.

You modestly place the number of consultants who should "sacrifice their dignity" at "fifty." I suppose this includes strugglers in both medicine and surgery; one could put one's finger on 25 strugglers in surgery or obstretrics, some of whom are doing well or are on the road to success, some hopelessly out of it, and too many of them hampered with the "premature brougham," in one or two instances a palpable "omne ignotum pro magnifico."

Good and early advice, such as that given by our old friend *Punch* to those about to marry—"don't"—should be freely circulated amongst our rising talent.

You, I fear, speak a little sarcastically in saying that "science no doubt would lose by it;" I should be inclined to think that we might be spared the weekly infliction of some of these unrecognised geniuses at certain of the societies, where they are regarded as an incubus, and as far as one may be allowed to form an opinion, their attempt at scientific investigation falls little short of a still more unsuccesful one at touting for the practice already absorbed by the few.

F.R.C.S.

[To the Editor of the Medical Times.]

DEAR SIR,—I have read with great interest the letter of M.R.C.P., in your last issue, and your remarks thereon. It appears to me that, in London at least, the present relative value of the different grades in our profession is not founded upon clear rational principles, and that the public are not to blame for failing to comprehend it. The result of which is a disastrous loss of both money and dignity to the most deserving members of the profession.

I myself, during the seventeen years that I have belonged to it, have puzzled my brains to know upon what logical grounds the "consultant," the hospital physician or surgeon, should *necessarily* be a superior person to the "general practitioner;" and where lies the loss of dignity in his doing what the latter does.

There doubtless were good grounds for a marked distinction in the days when the wisdom of our forefathers relegated the care of the health, as well as the education, of their nearest and dearest, to any one who chose to assume the functions of "doctor" or schoolmaster; the days when our art was supposed to be easily mastered, like other crafts, by apprenticeship; when "medicine" was cheerfully paid for, and "skill" counted cheap. In those days the intelligence of the nation saw no need for a better order of things, encouraged no better, deserved no better, and got no better. And the "consultant" of those days probably was far superior to any "general practitioner." But does anyone for a moment maintain that the scientific or practical knowledge of the average consultant of say fifty years ago was superior to that of an average M.D. of London or Edinburgh of to-day, albeit a "general practitioner?" The gap has been steadily narrowing, and is now more imaginary than real. I know certainly one man, whose name is far more widely and honourably known, both at home and abroad, than that of some whom I have heard abuse him as a "general practitioner;" who is certainly the most perfect ovariotomist that I have ever seen (and I have seen a good many operations, both at home and abroad), and whom I should prefer to any man I have yet seen, if I required any severe operation upon myself. Moreover, in general culture and refinement he might be followed with advantage by more than one consultant that I know. And there are many other general practitioners who have done good work for science, and who thoroughly maintain the dignity of the profession.

Now wherein lies the assumed superior dignity of the consultant? Is it that he works solely from disinterested devotion to science or humanity? Not so! for he as well as the G. P. works for gain. Is it that he absolutely abjures any two out of the three great departments of the profession? Not so! if I am to judge by one of the most distinguished of London Consulting Surgeons, who lately accepted eighty guineas for a country journey and his opinion upon a case that presented not a single surgical feature! Is it that he declines the sole charge of a case, and will not see it except in consultation with a G. P.? Not so, for he quite commonly does take entire charge from first to last of those who come to his consulting room! Is it that he expects to be waited upon at his consulting room, while the G. P. attends the patient at the latter's house? Perhaps, but as the greater immediate gravity of the case is what usually necessitates the latter arrangement, I fail to see how "dignity" is in any way sacrificed.

In a word, is not the whole assumed superiority of the consultant based rather upon *tradition*, than upon clear principles founded upon the facts of to-day? I do not for a moment mean to disparage the *leaders* of the profession—far from it. I bow my head in reverence to the consultant

who is a leader, but I deny in toto the assumption that a man is a leader because he is a consultant: "Dignitatibus viros dandos non dignitatis hominibus."

But our leaders require no caste privileges to maintain their pretensions to superiority. And what the public want is some better mode of estimating a man's abilities than the existing division provides. If qualifications were fewer in number and origin, and their relative value clearly understood by the public, it would not be so difficult as it now is for them to appraise a man's probable attainments. And why should not the highest qualifications attainable, let us say, only after a certain age, proof of good work done, and mature capacity, be the thing which determines the man's status, and the fees to which he is entitled? and that whether the patient go daily or weekly to the consulting-room, or the doctor go daily or weekly to the sick-room. Finally, I hold the real enemies of our dignity to be those who make the profession a mere cloak for commerce in drugs, or otherwise act unworthily—and no less those who encourage the public in the opinion that all of the profession outside of their caste is inferior to it in skill or culture.

I am, Sir, yours, etc., M.D.

Sir,—M.R.C.P.'s letter may, I think, be taken as a fairly representative one. I believe there is a strong and growing feeling among the younger physicians that they are placed at an unnecessary disadvantage by the practice of accepting minimum fees for interviews and consultations, which is retained by the leading men. It is almost needless to point out that the effect of this practice is inevitably to throw all consulting work indiscriminately into the later years of professional life, to burden those years with an excess of trivial routine, and to make it hardly possible for a physician under the age of forty to live by his profession.

I think the case is hardly met by your suggestion that some fifty superfluous physicians should quit the barren title of "consultant" and devote themselves to making an income in general practice. As long as the "consulting" status is held to convey an access of dignity our profession will afford a certain number of men in easy circumstances desirous of assuming the position without much regard to qualification or profit, and ready to undertake any kind of benevolent work that may seem to set a seal on their title.

But the present illogical system of uniform fees presses most hardly upon the very men who may most legitimately consider themselves entitled to rank as consultants; I mean on the men who, by dint of honest work, have pushed forward to positions on the staffs of the medical schools and leading metropolitan hospitals. Such men are seldom more than slenderly provided with private means, and find it hard measure that they should be required to compete for all they earn on equal terms with the whole body of their seniors. It is no artificial trade rule that is wished for to raise remuneration above its fair level. On the contrary, it is simply desired that the leaders of the profession should act in accordance with natural laws, and regulate their charges by the demand that exists for their services, as other men do. That they do not do so at present is doubtless the result of most praiseworthy motives, but, I venture to think, of most mistaken ones.

For it is not a question of personal interests only. The well-being of the profession, and of medical science, is being injuriously affected by the present unsatisfactory state of things. On the one side we see the elder men withdrawing themselves, to the astonishment of foreigners, from the work of investigation and teaching at a time when their experience is at its ripest, in order to reap the harvest that comes only late in life: on the other we see a number of the ablest students declining to enter the race for the higher places of the profession, which mean an indefinite number of years of poverty to any but a rich man. Between the two is seen many a struggling hospital physician, growing into middle life amid pecuniary difficulties, his horizon narrowed by the exclusive contemplation of hospital cases, the habits of private practice unacquired, himself often sorely tempted to trespass on the domain of the general practitioner, or to erect a new "specialty," or to advertise himself in one or other of the dubious ways that may divert a few guineas to meet some pressing need.

I cordially agree with you, Sir, that every effort should be made to increase the dignity and attractiveness of the general practitioner's position, and to make it more worthy of the class of men who now enter upon it; but here again the financial question comes to the front. As a body, general practitioners of medicine are excessively underpaid considering the character of their work. To improve the position, the first reform must be to raise the rate of remuneration along the whole line; and it is not easy to see how this can be effected while the public are aware that the advice of the most renowned consultants is to be had at so low a comparative rate.

I am, Sir, your faithfully,

Z.

Sir,—What a young man has to face on entering Medicine in the present day is competition with hospital work in two respects. He will find a comparison made to his disadvantage between his abilities and qualifications to treat patients, and those of "hospital men," and he will meet with those who consider hospital treatment much better than that outside such institutions. Further, the element of cheapness will be brought in, such "superior treatment!" being obtainable for *nothing*, or for giving a cheque to the charity when leaving it on recovery (which cheque, by the bye, never reaches any member of the medical profession), or by entering a "paying ward!" These he will find as daily vexations, and they are unjust vexations; for outside hospitals throughout the country there are to be found men who can compare most favourably for careful, safe, and successful work with those who are on hospital staffs, having passed through exactly the same courses of study, and having been tested by the same examinations, and holding the same diplomas, and possessing equal and oftentimes superior aptitude, but wanting only in the *influence* to get a place on a staff. Such men have further learnt that there are many points of departure from and improvements upon the *treatment* of disease as conducted in hospitals, attention to which points is of the utmost value to patients with reference to recovery or not. The experience of cases and their ultimate issues gained by such men is more complete and thorough than that gained in mere hospital practice: patients being watched in the one case over a period of years, in the other case seen for a short time only. It is quite a fallacy to suppose that either the best diagnosis or the best treatment is to be found in hospitals. Many cases which die in hospitals would recover in the worst of homes, as the late Sir J. Simpson, of Edinburgh, said. Then, with reference to cheapness: this competition on the part of charities is an abomination, and means ought to be found to put a stop to it. Medical men ought not to be found who will hold positions in establishments favouring such unfairness. The motives to do hospital work are not charitable purely, as mentioned in the extract from an American Journal in the *Medical Times* of January 5, 1884, page 15: "It is well known that it is not performed from motives of charity, but for the position which is gained by being attached to a hospital staff, and the hopes of a good practice ultimately accruing therefrom."

One way to improve matters would be for every medical man, as opportunity might arise, to explain to his patients, hospital and dispensary these weaknesses and disadvantages, and their name is legion; and another point which the younger men might attend to, would be to carry out the Cottage Hospital plan, with pay, *and thoroughly good pay*, too, attached, and equal division of the pay, work, and honour amongst all the medical men in a district. Such institutions would further furnish clinical instruction for pupils, certainly quite equal to that met with in hospitals.

One word in conclusion—*united effort* amongst the younger men is the best way for them to improve their social and monetary position, and thus bring an increasing share of happiness to themselves and their families, which is justly their *right*, instead of penury and dependence.

With reference to fees, it might be useful if a table of minimum fees, not too cumbersome, could be agreed upon jointly by the Colleges of Physicians and Surgeons, so that men might have good authority for asking for sufficient remuneration, and, as in the Law, where necessary, fees to be paid first.

London, *January* 9, 1884. P.

THE REMEDY FOR SEWER SMELLS.

[To the Editor of the Medical Times and Gazette.]

SIR,—I have read your annotation upon sewer smells in the last number of your Journal with the greatest satisfaction, as it gives the pith of my teaching in this place for the past twenty years, and as I have, now and then, endeavoured to show in your columns and elsewhere, viz., that if the sewers are properly laid and well flushed they will not smell; that if there are smells from sewers it is the fault of the construction.

Free ventilation is a necessity, and the more free the less chance of evil. It is most unwise to bottle up the results of decomposition, as is so frequently done because a ventilator gives out a smell at a certain point.

My object in writing to you on this occasion is to point out to my medical brethren that the remedy lies in the appointment of efficient officers by local authorities. That whilst the Local Government Board gives its sanction to the construction of drainage works by men who know nothing of the first principles of sanitary science, it will continue to be necessary to reconstruct the sewers of that district at a greatly enhanced cost, after mischief has been done by those sewers which have been laid in opposition to the teachings of sanitary science. The Sanitary Institute of Great Britain has been founded to remedy this defect. The diplomats of that body have shown their ability to perfect drainage works on right principles, and it would be immensely to the interest of the public service if all local authorities would insist upon their surveyors and inspectors of nuisances possessing the qualifications of the Institute before they were entrusted with the duty of constructing works which have an immense influence for good or evil upon the health of the district in which those works are required. I wish I could persuade medical officers of health to support the Institute by becoming members of it.

I am, &c.,

ALFRED CARPENTER,
Chairman of the Council.

Croydon, December 31, 1883.

MEDICAL NEWS.

APOTHECARIES' HALL. — The following gentlemen passed their examination in the Science and Practice of Medicine, and received Certificates to Practise, on Thursday, 3rd January, 1884:—

George Augustus Lovelace Bowling, Sewardstone-road, E.
Frederick William Hatchett, Upper Cheyne-row, Chelsea, S.W.
William Murray, Wray Crescent, Tollington-park, N.
James Norman Vogan, St. Bartholomew's Hospital, E.C.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—The following gentlemen passed their primary examinations in Anatomy and Physiology at a meeting of the Board of Examiners on the 7th inst., and when eligible will be admitted to the pass examination, viz.:—

Anglin, W. G., student of Kingston, Canada.
Biggam, W., of the Newcastle School.
Cossens, W. H., of the Cambridge School.
Denike, G. H., student of Kingston, Canada.
Facey, W. E., of the Cambridge School.
Hewish, E. M., of the Toronto School.
Hughes, H. G., of the Dublin School.
Miller, W. F., of the University of Melbourne.
Percival, A. S., of the Cambridge School.
Roll, G. W., of the Cambridge School.
Stopford, R., of the Liverpool School.
Whitaker, J., of the Edinburgh School.
Yeld, W. H., of the Manchester School.

Nine candidates, having failed to acquit themselves to the satisfaction of the Board of Examiners, were referred to their studies for three months, and one for six months.

MANCHESTER MEDICAL SOCIETY.—At the Annual Meeting held at the Owens College, January 9th, 1884, the following office-bearers were elected:—

President: Daniel John Leech, M.D.
Vice-Presidents: John Augustus Ball, M.B. (Stockport); Julius Dreschfeld, M.D.; James Hardie, M.D.; Thomas Jones, M.B.
Treasurer: David Little, M.D.
Secretary: Charles James Cullingworth. M.D., 260, Oxford-road, Manchester.

FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.—The Council of the Faculty have appointed Professor HAMILTON, of Aberdeen, Faculty Lecturer for the year. The subject of the course will be, "The Structure and Functions of the Brain in relation to Disease."

DEATHS.

JONES, WALTER, M.D., formerly of Finsbury Square, at 15, Ladbroke Square, W., on January 5, aged 66.
TEMPLE, JOHN DE LIEFDE, M.D., on January 2, aged 41.

THE BOWER AND KEATES CASE.

The Secretaries desire to remind the members of the profession that the list of subscriptions to the Indemnity Fund was closed on Jan. 5th. They also wish to state that the secretarial work will be greatly facilitated if those intending to sign the memorial will do so and return it to the College of Physicians before Saturday, the 19th inst.

In reply to many letters, it seems necessary to point out that the acknowledgments of subscriptions in the journals cannot be brought up to date of publication owing to the large number of letters received and the pressure of space.

It may be of interest to state that copies of the statement were sent out by the Committee to members of the profession residing in the United Kingdom whose addresses appeared in Messrs. Churchill's Directory for 1883, their number being about 18,500, and in reply to these 1,662 letters were received up to Friday, Jan. 4th (the date to which this week's list is brought), enclosing subscriptions, also 253 letters enclosing signatures to the memorial; 454 were returned through the dead-letter office, of these 320 were stated to have gone away and left no address; 74 were deceased, and 60 declined to receive the letters; these, however, were all redirected envelopes.

The following contributions (fifth list) were received up to Friday, Jan. 4th, the remainder will be acknowledged as soon as possible.

(Signed)

F. A. MAHOMED.
R. W. BURNET.

A. E. Durham, F.R.C.S., £10 10s.; Sir W. Bowman, £5 5s.; G. T. Gream, F.R.C.S., £5 5s.; H. Rickards, M.D., £5 5s.; G. O. Rees, M.D., F.R.S., £3 3s.; F. T. Roberts, M.D., £3 3s.

The following have sent two guineas each:—H. M. Baker, F.R.C.S.; J. Brockwell, Esq.; R. B. Carter, F.R.C.S.; T. A. Cott, M.A.; Charles Coates, M.D.; W. H. Freeman, Esq.; W. C. Grigg, M.D.; W. J. Harris, Esq.; Herefordshire Medical Association; Grailey Hewitt, M.D.; Charles Higgins, F.R.C.S.; Messrs. Kellock and Reynolds; J. P. Langshaw, F.R.C.S.; G. Lund, M.D.; G. Lichtenberg, Esq.; H. Osborne, Esq.; G. V. Poore, M.D.; P. H. Pye-Smith, M.D.; R. H. Semple, M.D.; E. H. Sieveking, M.D.; E. P. Sharkey, M.D.; Pugin Thornton, Esq.; M. H. H. Vernon, Esq.; F. Weber, M.D.; A. Willett, F.R.C.S.; E. J. Winterbottom, Esq.

Messrs. Taylor and Dunbar, £1 10s.; M. Brownfield, Esq., £1 5s.

The following have sent one guinea each:—W. A. Adams, F.R.C.S.; J. F. Anderson, M.D.; F. Argles, Esq.; Messrs. Ashurst, Tucker, and Smith; C. E. Baker, Esq.; A. E. Barker, F.R.C.S.; F. Barnes, M.D.; R. Barwell, F.R.C.S.; H. C. Bastian, M.D.; Adam Bealey, M.D.; Marcus Beck, M.B.; C. T. Blackman, Esq.; J. R. Bosworth, Esq.; Percy Boulton, M.D.; Essex Bower, M.D.; Henry Bott, Esq.; Thomas Bridgwater, M.B.; J. S. Bristowe, M.D.; Messrs. Brookes Bros.; C. T. Brookhouse, M.D.; R. Brown, Esq.; R. Brown, F.R.C.S.; F. G. Broxholme, M.D.; C. Budd, M.B.; J. E. B. Burroughs, Esq.; G. R. Burtt, Esq.; T. C. Cade, Esq.; C. C. Carter, M.D.; W. Cayley, M.D.; E. Chaffers, F.R.C.S.; F. H. Champneys, M.B.; J. D. Chepmell, M.D.; E. F. Chinery, F.R.C.S.; R. H. Clay, M.D.; W. F. Cleveland, M.D.; E. M. Cooke, M.B.; J. Couldrey, Esq.; E. H. Cree, M.D.; J. Croft, F.R.C.S.; M. Davis, M.D.; W. H. Day, M.D.; W. H. Dickenson, M.D.; W. A. Dingle, Esq.; A. R. Dodd, Esq.; H. B. Donkin, M.B.; C. H. Drake, Esq.; T. Eastes, M.D.; J. Fairbank, Esq.; Wm. Fairbank, Esq.; E. A. Fardon, Esq.; Sir J. Fayrer, M.D.; J. R. Fielding, Esq.; C. E. Fitzgerald, M.D.; A. Freer, Esq.; C. C. Fuller, F.R.C.S.; R. Fyson, Esq.; F. J. Gant, F.R.C.S.; F. H. Gervis, Esq.; J. R. Gibson, F.R.C.S.; C. Godson, M.D.; F. W. W. Goodsall, M.D.; W. Goodson, Esq.; F. C. G. Griffin

M.B.; F. de H. Hall, M.D.; J. Hardie, M.D.; H. Harrison, Esq.; T. W. Haslehurst, Esq.; R. Heath, M.D.; F. H. Hodges, F.R.C.S.; C. Holding, F.R.C.S.; T. F. Hopgood, Esq.; T. A. J. Howell, Esq.; W. P. Huggard, M.A.; H. S. Hughes, Esq.; J. R. Humphreys, F.R.C.S.; G. M. Humphry, M.D.; H. J. Hunt, Esq.; Evan Jones, Esq.; J. Jones, Esq.; J. B. Kennedy, Esq.; G. R. Lake, Esq.; Chas. Lewis, Esq.; H. R. C. Litchfield, Esq.; R. Clement Lucas, F.R.C.S.; A. V. Macan, M.B.; W. McCheane, F.R.C.S.; M. M. McHardy, F.R.C.S.; F. B. Mallet, M.D.; F. Manser, Esq.; N. D. Markham, M.D.; C. H. Marriott, M.D.; C. Pearce, M.D.; T. S. Palmer, M.D.; F. Peirce, M.D.; A. Perigal, M.D.; O. Pemberton, F.R.C.S.; *Sir* H. A. Pitman, M.D.; G. B. Powell, Esq.; L. L. Powell, Esq.; J. S. Ranking, M.D.; T. Rayner, M.D.; J. C. Roberts, Esq., W. B. Robertson, M.D.; E. T. Roe, M.D.; A. Roper, Esq.; J. Harris Ross, M.D.; B. Both, F.R.C.S.; Jas. Riley, Esq.; Geo. Roper, M.D.; J. K. Sampson, Esq.; A. E. Sansom, M.D; L. W. Sedgwick, M.D.; H. Sewell, Esq.; J. Shaw, M.D.; D. Shier, M.D.; T. Wood Shortridge, Esq.; F. H. Simpson, F.R.C.S.; E. H. Slakeney, F.R.C.S.; Messrs. Smart and Moore; Alder Smith, F.R.C.S.; W. H. Smith, Esq.; E. Snell, Esq.; R. Southey, M.D.; E. J. Spitta, Esq.; Messrs. W. S. W. and J. E. Square; J. S. Stocker, M.D.; J. M. Stothard, Esq.; H. G. Sutton, M.D.; J. Sykes, M.D.; Chas. Taylor, M.D.; Frederick Taylor, M.D.; Herbert Taylor, M.B.; John Taylor, Esq.; Thos. Taylor, F.R.C.S.; W. B. Taylor, M.R.C.S.; G. Tegart, Esq.; M. Thomas, Esq.; Disney L. Thorp, M.D.; M. Tonge, M.D; W. C. Toulmin, Esq.; J. Tweedy, F.R.C.S.; C. E. Underhill, M.B.; J. Waggett, M.D.; A. D. Walker, M.D.; W. D. Wathen, Esq.; W. Weir, M.B.; — Wallace, Esq.; C. A. West, M.D.; T. Whipham, M.B.; W. H. White, M.A.; D. M. Williams, Esq.; E. Woakes, M.D.; R. H. Woodhouse, Esq.; J. C. Worthington, Esq.; E. Percival Wright, M.A.; W. T. Wyatt, M.A.; E. Williams, Esq.; W. B. Young, Esq.

The following have sent one pound each:—George Burn, M.B.; W. G. Church, F.R.C.S.; F. D. Dyster, M.D.; Messrs. A. and W. Eddowes; W. M. Harmer, Esq.; A. C. E. Harris, M.B.; F. W. Humphreys, F.R.C.S.; Hermann J. Jones, M.D.; W. H. K. Kane, M.D.; D. Kennard, Esq.; R. McDonnell, M.D.; J. E. Tuxford. Esq.; J. F. Walker, Esq.; G. M. Whitehead, Esq.; C. T. Wickham, Esq.

W. L. Mackesey, Esq., fifteen shillings.

The following have sent half a guinea each:—J. Ackery, Esq.; E. Creswell Baber, M.B.; M. Balding, M.D.; M. Benoly, M.D.; J. Bevan, M.B.; C. Y. Biss, M.B.; T. Bowling, Esq.; C. J. Bracy, M.B.; H. M. Brewer, Esq.; J. Braithwaite, M.D.; H. Briggs, Esq.; J. Bunny, M.D.; J. B. Bunny, Esq.; R. E. Carrington, M.D.; E. Child, Esq.; R. M. Chisholm, Esq.; G. Goates, M.A.; W. S. Colby, Esq.; J. B. Caskie; J. G. Creasy, Esq.; R. Creamer, Esq.; John Crew, Esq.; G. C. Dale, M.D.; W. J. Daniel, Esq.; R. Davidson, M.B.; De la Cowe, M.D.; F. Dawtrey Drewitt, M.D.; J. E. Ellerton, Esq.; J. J. Emerson, Esq.; Chas. Firth, M.D.; J. C. Fish, M.D.; John Forrest, M.D.; Geo. C. Franklin, F.R.C.S.; R. L. Freer, Esq.; J. C. Galton, M.A.; R. E. Gaye, Esq.; W. Kitto Giddings, M.D.; R. W. Goldie, Esq.; T. Stokes Guppy, M.D.; A. H. B. Hallowes, Esq.; A. Harvey, M.D.; R. W. Henderson, Esq.; G. Jackson, F.R.C.S.; Osborne Johnson, Esq.; F. W. Jordan, Esq.; J. S. Kane, B.A.; Norman Kerr, M.D.; R. B. Kidd, Esq.; G. Lamb, Esq.; J. W. Lane, M.D.; J. Leigh, F.R.C.S.; C. Lovegrove, Esq.; Luke Newry, Esq.; H. S. Leverton, Esq.; F. F. Lloyd, Esq.; J. McClelland, M.D.; J. Macfee, M.D.; A. Matcham, Esq.; G. A. Meaden, Esq.; J. Miller, M.D.; J. R. Milsome, M.D.; G. B. Morgan, Esq.; R. Paramore, Esq.; T. D. Patmore, Esq.; — Perkins, Esq.; F. S. Pilkington, Esq.; H. F. M. Pope, Esq.; Rees Powell, Esq.; B. L. Powne, Esq.; D. G. Prothero, M.D.; Chas. Puzey, Esq.; John Rae, Esq.; J. M. Randle, Esq.; T. Richardson, Esq.; W. E. Robbs, M.B.; W. R. Rogers, M.D.; G. Philip Rugg, M.D.; A. Shipton, Esq.; W. P. Shipton, Esq.; Simeon Snell, Esq.; A. Storrs, M.D.; D. T. Thomas, Esq.; W. A. Thomson, F.R.C.S.; W. Walker, F.R.C.S.; S. Warren, M.D.; W. D. Wilkes, Esq.; F. Whitwell, Esq.; G. G. Whitwell, M.B.; R. H. Williams, Esq.; M. A. Wood, F.R.C.S.; A. W. Wordly, Esq.; T. A. Wotherspoon, M.D.; C. St. John Wright, M.B.

The following have sent ten shillings each:—J. A. Aitkens, Esq.; W. H. Allchin, M. B.; J. W. Anningson, Esq.; Alex. Ballantyne, M.D.; G. R. Barnes, M.D.; F. A. Best, Esq.; R. A. Biliald, Esq.; W. E. Baylie, Esq.; G. Birt, M.B.; F. Blackman, Esq.; R. Blaikie, Esq.; A. R. H. Bland, M.D.; W. H. Booth, Esq.; F. A. Bond, M.B.; R. E. W. Brewer, Esq.; C. E. Brown, M.B.; R. Buswell, Esq.; J. Brown, Esq.; J. Browne, J.P.; T. J. Burroughs, M.D.; H. Buss, M.D.; William Carter, M.D.; L. Clapham, Esq.; T. Clark, Esq.; B. Clarke, F.R.C.S.; G. B. Collett, Esq.; J. Cook, M.D.; C. W. Cooper, M.B.; A. Cooper, Esq.; R. Corbet, Esq.; M. A. B. Corbin, F.R.C.S.; G. G. Corbould, Esq.; D. Cowie, M.D.; G. H. Coveney, Esq.; Edgar Cox, Esq.; C. P. Creed, Esq.; W. H. Crossley, Esq.; G. H. Daly, M.D.; C. Davidson, F.R.C.S.; G. H. Davis, Esq.; A. D. Deane, Esq.; J. Dearden, M.D.; R. B. Dunlop, Esq.; B. Edwards, Esq.; W. England, M.D.; W. Evans, Esq.; Abel Evans, Esq.; H. Evison, Esq.; T. R. Fendick, Esq.; J. S. Ferris, M.B.; R. W. Garnham, Esq.; J. H. Gordon, Esq.; J. H. Gornal, Esq.; T. A. Gray, Esq.; A. C. Grieve, Esq.; E. Halford, F.R.C.S; R. S. Hanbury, M.D.; A. Harnet, Esq.; V. D. Harris, M.D.; E. Harrison, Esq.; W. H. Hartill, Esq.; R. Heslop, Esq.; G. C. Hope, M.D.; W. E. Hill, M.D.; J. P. Hodgson, M.D.; C. W. Izod, Esq.; J. Jackson, Esq.; J. F. Jackson, Esq.; C. Jewell, Esq.; F. E. Jones, M.D.; F. J. Joynes, Esq.; J. E. Kent, Esq.; H. W. Kiallmark, Esq.; C. King, Esq.; J. Kirkman, M.D.; H. J. Knight, Esq.; H. M. Langdale, Esq.; H. Lapton, Esq.; J. Lampton, F.R.C.S.; E. J. Leverton, Esq.; M. Lloyd. Esq.; J. Loane, Esq.; S. Lockie, M.D.; S. P. Lowdell, Esq.; J. G. Longstaff, M.D.; W. C. Luffman, Esq.; A. Maclean, F.R.C.S.; R. C. Maclagan, M.D.; S. W. McDowall, M.D; E. McCraith, Esq.; G. Mackay, M.D.; S. R. Manby, Esq.; G. May, M.B.; T. H. Meikee, M.D.; R. H. Meade, F.R.C.S.; G. Mickley, M.A.; H. Moore, Esq.; J. E. Morris, Esq.; A. Morison, M.D.; T. Morton, M.D.; W. W. Morgan, M.D.; W. Mott, Esq.; A. W. Nankivell, F.R.C.S.; T. Nash, Esq.; W. Neal, Esq.; C. Nind, Esq.; F. Nicholl, M.D.; L. J. O'Neill, F.R.C.S.; C. Orton, M.D.; J. A. Owles, M.D.; J. M. Owen, Esq.; J. Page, Esq.; G. C. Parnell, Esq.; E. H. Pettifer, Esq.; E. B. Pellew, Esq.; H. Piers, Esq.; T. H. Redwood, M.A.; C. J. Renshaw, M.D.; R. L. Roberts, M.D.; J. W. Rougton, Esq.; D. Russell, M.D.; J. W. Roe M.D.; C. K. Rudge, Esq.; A. Samuelson, M.D.; W. J. Scofield' Esq.; W. B. Sealy, Esq.; W. Shaw, Esq.; M. Shirley, Esq.' F. D. A. Skae, M.D.; H. J. Skelding, Esq.; W. A. Smith, M.A.; J. F. Stafford, Esq.; S. H. Steel, M.B.; M. Steele, M.B.; G. H. Symes, M.D.; J. Thompson, Esq.; T. W. Thursfield, M.D.. F. Trevan, Esq.; W. M. Tronsdale, F.R.C.S.; G. St. G. Tyner; F.R.C.S.; C. S. Vachell, M.D.; C. Walter, Esq.; J. Watson, M.D., G. T. B. Watters, M.D.; S. H. Webb, F.R.C.S.; A. M. Wedderburn; M.D.; G. F. Wellingliston, M.D.; W. F. West, Esq.; A. Wheeler, Esq.; H. Williams, Esq.; W. Wood, F.R.C.S.; J. L. Worship, Esq., R. Wotton, Esq.; J. K. Wynne, M.D.

The following have sent seven shillings and sixpence each:—; H. Malins, M.B.; T. D. Paradise, Esq.; W. Sankey, M.D.

The following have sent five shillings each:—H. Adcock, Esq. F. R. T. Allen, M.D.; H. E. Armstrong, Esq.; H. A. Auchineek' F.R.C.S.; E. G. Bartlam, F.R.C.S.; M. S. Barton, Esq.; E. W. Bawtree, M.D.; C. W. Beresford, Esq.; H. Bingham, M.D.; A. A. Blakiston, Esq.; G. F. Blake, Esq.; O. Bowen, Esq.; J. Boyton, Esq. W. A. Brailey, M.D.; — Brooks, —; J. S. Bootiman, Esq.; A. Boswell' M.D.; A. H. Buck, Esq.; T. A. Buck, M.B.; E. G. Bull, Esq.; C. G. Bunn, Esq.; W. M. Burman, Esq.; P. B. Burroughs, Esq.; J. S. Berry' M.D.; J. Carnegie, M.A.; T. Cary, Esq.; E. Casey, M.D.; T. Cassan' Esq.; H. N. Chilcote, Esq.; J. Clare, Esq.; A. C. Clarke, M.D.; R. T. Cobbold, Esq.; F. Coley, M.D.; F. E. Cockell, Esq.; E. Cook, Esq.; J. W. Craig, M.D.; J. Crerar, Esq.; G. Crichton, M.D.; A. Crighton M.D.; J. R. Crease, F.R.C.S.; A. Croker, Esq.; T. P. Daniel, Esq.; W. E. Dickinson, Esq.; R. Douglas, M.B.; W. N. Drury, M.D.; W. Duncan M.D.; S. Edwards, Esq.; M. J. Egarr, Esq.; G. H. Elliott, Esq.; G. Foote, Esq.; J. Ford, Esq.; J. Fraser, M.D.; J. W. Fry, Esq.; W. F. Fryer, M.D.; L. Fuller, Esq.; J. E. Games, M.D.; A. N. G. Gibbs, Esq.; J. Gibson, M.B.; B. F. Worrall, M.D.; M. Tuke, Esq.

Other smaller sums have been received from A. Macaulay, M.B.; J. Walton, M.B.; A. Pearse, M.D.

F. A. Mahomed, R. W. Burnet, } *Hon. Secs.*

THE ROGERS TESTIMONIAL.

The following is the eleventh list of subscriptions:—Dr. Henry Drinkwater, Sunderland, £1 1s.; C. H. Buncombe, Esq., F.R.C.S., City of London Infirmary, £1 1s.; Dr. Montague Thomas, Nottingham-place, Regent's-park, £1 1s.; F. Sadd, Esq., Rugby, £1 1s.; Dr. Milsome, Addlestone, 10s. 6d.; Dr. Robert Tiffen, Wigton, 10s. 6d.; E. Snell, Esq., Ketton, Stamford, 10s.; Dr. Turtle, Woodford, 10s.; Geo. Harrison, Esq., White Friars, Chester, 5s.; C. Read, Esq., Stradbroke, 5s.; Dr. T. J. Hughes, Woolwich, 5s.; Dr. R. T. Jones, Harlech, 5s.; Dr. E. T. Thompson, Wolston, Coventry, 5s.; W. Arras, Esq., Wetheral, 5s.; Dr. Lush Fyfield, Andover, 10s. 6d.; W. Moore, Esq., Stourport, 10s.

THE HIND FUND.

The following additional subscriptions have been received and paid to the account of the "Hind Fund" at Messrs. Coutts' Bank:—H. R. O. Cross, Esq., A.M.D., £1 1s.; Dr. Robert Cross, £1 1s.; from India (per T. d'O. Partridge, Esq.), £5 5s. 10d.; Dr. W. C. Hoffmeister, £1 1s.; Dr. Wm. J. H. Lush, £1 1s.; G. E. G. Metcalfe, Esq., £1 1s.; Eustace M. Swanwick, Esq., £2 2s.

Subscriptions may be paid to Dr. Richardson, F.R.S. (chairman), 25 Manchester-square; John Tweedy, Esq., F.R.C.S., 24, Harley-street (hon. treasurer); A. J. Pepper, Esq., F.R.C.S., 122, Gower-street; and T. Wakley, jun., Esq., L.R.C.P., 96, Redcliffe-gardens (hon. secretaries); or to Messrs. Coutts & Co., Strand.

NOTES, QUERIES, AND REPLIES.

Primary Examinations.—The following were the questions on Anatomy and Physiology submitted to the candidates for the diploma of member of the Royal College of Surgeons, at a meeting of the Board of Examiners on the 4th inst., when they were required to answer four, and no more, out of the six questions on each subject—viz., Anatomy (from 1 to 3 o'clock p.m.):—1. Describe the ligaments which connect the atlas and axis together, and also those which connect these bones with the occiput. 2. Describe the dissection required to expose the pronator quadratus muscle. 3. Describe the first rib. 4. Describe the position and relations of the liver, mentioning especially the extent to which it is covered by peritoneum, and the manner of its connexion with the walls of the abdomen and surrounding viscera. 5. Mention in their relative position the various structures which are exposed by removing the gastrocnemius and soleus muscles. Give the attachments of any muscles you may mention. 6. Describe the ophthalmic artery and its branches.—The following were the questions on Physiology (from 4 to 6 o'clock), viz.:—1. Give a classification of food-stuffs; state the changes which the proteids undergo during gastric and duodenal digestion. 2. What is meant by arterial blood-pressure? How is it modified locally and generally? 3. What are the sources of animal heat? Explain the mode in which a constant temperature is maintained in warm-blooded animals. 4. What is the structure and distribution of non-striated muscle? How does it differ in its mode of action from striated muscle? 5. Describe the microscopic appearances of a transverse section of the spinal cord. What are the functions of the parts you name? 6. Describe the normal rhythm of the respiratory movements. Explain the nervous mechanism by which it is regulated.

A Provincial Teacher.—Two hundred and eleven candidates presented themselves for the primary or anatomical and physiological examination for the diploma of membership of the Royal College of Surgeons on the 4th inst., against one hundred and ninety at the corresponding period last year. The names and the schools of the respective candidates are published in the *Medical Times*.

Mr. Thompson.—An examination for the License in Dental Surgery of the Royal College of Surgeons will be held in the ensuing month.

Dr. Edgerton, Middletown, Connecticut, U.S.A.—Letter and enclosure received with thanks.

A. G. Hakim, Esq., Mhaswad, India.—Post-card and money-order received with thanks.

Dr. Jacob Chunder Banerjea, Santipur, Bengal.—Letter and enclosure received with thanks.

COMMUNICATIONS RECEIVED—

APPOINTMENTS FOR THE WEEK.

14. *Monday.*

MEDICAL SOCIETY. Mr. Pick will read a paper "On Amputation at the Knee-joint, by means of Lateral Flaps." Professor Alexander Ogston (of Aberdeen), a paper "On a New Operation for Flat Foot." Dr. Day will show a case (in the Library)—"Pulmonary Stenosis in a Child."

ODONTOLOGICAL SOCIETY OF GREAT BRITAIN, 40, Leicester Square, W.C.—The Meeting of the above Society wrongly announced for January 7th, will take place Monday, January 14th, at 8 P.M.

15. *Tuesday.*

ROYAL INSTITUTION, 3 p.m. Mr. R. S. Poole—"Coins and Medals."

17. *Thursday.*

ROYAL INSTITUTION, 3 p.m. Professor Pauer—"Music for the Pianoforte, &c."

HARVEIAN SOCIETY OF LONDON, 8.30 p.m. Annual General Meeting; President's Address; Election of Officers; Conversazione.

18. *Friday.*

ROYAL INSTITUTION, 9 p.m. Professor Tyndall—"Rainbows."

THE MEDICAL SOCIETY OF CHARING CROSS HOSPITAL, 8 p.m. Mr. C. W. Heaton, "On some Points in Urine Analysis."

19. *Saturday.*

ROYAL INSTITUTION, 3 p.m. Professor Morley—"Life and Literature under Charles I."

CLINICAL LECTURES

By J. MATTHEWS DUNCAN, M.D., F.R.S.,

Physician-Accoucheur and Lecturer on Midwifery at St. Bartholomew's Hospital.

LECTURE IV.

ON SOME MINOR AILMENTS.

WHEN I use the term "minor ailments" to designate the subject of this lecture, I take the physician's, not the patient's, point of view. To her the matter in hand, however slight in the physician's estimation, is most interesting and important, and cannot be, without care, spoken of as minor. Such ailments may be painful and grievous while they last, but they do not destroy general health, and they are not fatal.

Patients are often very inquisitive into the causes and nature or importance of diseases, and physicians are sometimes too facile in naming them, or in concurring with patients regarding them. Here, as on many other occasions in the course of medical practice, the physician should be firm in adhering to pure truth, not forgetting that all kinds and degrees of falsehood, all half-true statements, even when made with good motives, all statements, true only as so many words, should be avoided, should also be abominable in his eyes. It is true, and never to be forgotten, that a lie is always a lie, and never does the greatest good, now or in the future; always does harm, now and in the future. Never allow yourselves to be shaken in these principles by desire of any kind of time-serving. Great medical men have boldly taught that the physician may not only conceal the truth, but, in certain circumstances, declare a lie. I avoid mentioning the name of one most highly respected, who advises this course in the case of cancer of the liver, asserting that the entertainment by the patient of false views as to the nature or danger of his disease, will materially and favourably modify its course, and secure temporary ease of mind for him. The pathology, therapeutics, and morality are, I believe, all most bad: experience has taught me quite otherwise; and, besides, if you allow yourself to lie once, why not ten times? There are cases in casuistry in which you may be driven to make a statement that is not true, but they almost never occur in medical practice; and the only justification of this conduct is the avoidance of a graver falsehood, for there are degrees of importance of lies. You have it always in your power to be silent, and it is scarcely possible to construct a lie out of that negative. If you wish to impress your patient with a due sense of the gravity of her case, you may do so without bluntly surprising her with a terrible announcement, as by calling a consultation, or using some other such indicative or preparatory measure.

I make these statements preliminary to some remarks on minor ailments, because it is more frequently in them than in graver ailments that patients are injuriously, and, I am sorry to say, often cruelly misled.

I have said that patients are often ingenious and inquisitive as to causes: the physician is most anxious to forecast consequences. With this forecast or prognosis, so far as he is concerned, I have now nothing to do. But his patient is sure to ask questions regarding

her fate, or to argue regarding the gravity of her case from his expressions, oral or other, and from his conduct. In every case a physician is instructing his patient regarding her disease; and if he instruct her badly, he may cause her much evil. In the case of minor ailments it is common for this evil to be produced by an exaggerated anxiety, or by a costly and perhaps fussy and frequent interference of the physician. Many minor ailments are in this way generated or aggravated, or rendered inveterate—cases that a little kindly consideration and careful conversation would dissipate, are changed from molehills into mountains.

You will meet with cases of amenorrhœa in healthy girls, whereof the cure is sought with an enthusiasm that is explained only by perhaps accidentally finding out that the patient or her guardian regards it as a disease of the highest degree of gravity. A woman with no uterine complaint whatever, and in perfect health, is told that her womb is displaced, and immediately she is transformed into a great sufferer eager for cure, willing to endure the martyrdom of enforced rest and local treatment to gain what can never be gained in that way; she has been badly instructed by her physician, and this bad instruction will render her return to health a matter of great difficulty, a result to be secured only by overthrow of her confidence in her previous instruction. Cases are quite common where women have great pain and misery, which are entirely "imaginary" as they say, yet real, and which are cured at once by the assurance pressed into their minds that they have not cancer—by their abandoning an erroneous idea.

There are many minor ailments, chiefly in the form of aches or pains, for which the best treatment is to coax the patient into neglect of them. Let them alone as far as possible, for the more attention is drawn to them the worse they will be, and the longer will they last.

To deal wisely and boldly with minor ailments, it is necessary that you should previously make yourself well assured as to their nature—that they really are minor, and, if possible, exactly what they are. Often you cannot ascertain what they are, while various conditions of them satisfy you that they are minor.

Neuralgia of a Labium.

I have never seen any neuralgia more intense than that of the cord in the male. One case in a clergyman I can never forget, it was so very severe. In woman I have only seen it distinctly a few times. The worst case was that of a stout old lady liable to bronchitis and asthma. In her it came only occasionally, but when it did come it was so severe as to cause much alarm; the pain ran along the cord or rather the round ligament in the right inguinal canal, and was most severe in the corresponding labium. It was soothed by kind attention, hot bathing being generally used, sometimes anodyne applications to the skin.

Commencing Hernia.

All pains about the external inguinal opening are not neuralgic, nor inflammatory. I remember well the case of a sensitive young lady whose pains had been very puzzling to her physician, who had reasons for avoiding strict local inquiries. She was indeed sent to me to have these inquiries made, because much and varied treatment by medicines and rest had failed to give any relief. The pain was confined to the region of the femoral opening on one side; rest removed it, exertion induced it, coughing made it worse; and a strong impulse was felt in the part by the hand applied when a deep cough was made. Knowledge of the seat and cause of the pain was nearly enough for its cure; and complete relief was got by wearing a truss. Cases of a like kind are not very rare.

Neuralgia of Bone.

When a bone of the pelvis has been injured, the part, sometimes after complete recovery so far as manipulative examination is concerned, retains a morbid sensitiveness or weakness. It is not swollen; but it is liable to ache severely or be painful. Cases of this kind in bones of the limbs I have known to be successfully treated by laying the bone bare by knife, raising the periosteum, and gouging or chiselling off the surface of the affected part. In my cases I have not resorted to this, and I may best and most briefly tell you all I know of the matter by giving a few details of two.

A fine healthy young woman had a first labour, managed by a skilful accoucheur, natural in all respects, except that delivery was completed by short forceps. At the time of delivery nothing special was noted as to wounding; but the patient felt a deal of pain in the private parts, on the left side, during all her recovery. She got up, however, and was well and strong; but as soon as she began to walk, the pain in the left labium recurred, and was increased in severity as she increased the use of her legs. The pain was now ascribed to weakness, now to falling of the womb, now to ulceration, and was treated accordingly, but with no good effect. Careful local investigation discovered the labium to be internally cleft, and the deepest part of the cleft quite healed, healthy looking, but adhering to the descending ramus of the pubes. The bone was scarcely tender, but whenever it was touched, the patient at once, and again in subsequent examinations, declared that that, and that alone, was the seat of pain. The bone was occasionally tender after great exertion, as in dancing: it was always and exclusively the seat of the aching pain. The labium had been cut by the anterior margin of the left blade of the forceps, and healing had taken place with adhesion of the cicatrix to the subjacent bone. Complete satisfaction as to the seat and nature of the disease was half the cure. Avoidance of long walks and of much dancing, hot bathing at bedtime, tonics, iodide of potassium, were all used, and did not bring quick relief. It was not till these cures had been continued more than a year that the whole matter was forgotten. Now she never feels it.

A middle aged woman, a clergyman's wife, was thrown out of a little pony phaeton, and fell on her sacrum. After the accident she had continued pain in it for a long time; and the pain recurred after intervals of health varying in length. When it came, she felt the part to be a little tender, but not swollen. Latterly, after some years, she was led to believe that now her suffering was not from the injury, but from some disease of the womb. Then she consulted me, and it was very easy to make out that the pain was in the bone, exactly where the injury had been inflicted. There was no uterine disease, and the conclusion was inevitable that the case was one of neuralgia consequent on mechanical injury. With assurance on this point she was quite satisfied, and went away with some directions as to treatment when the aching came on.

Perhaps this disease should be called chronic ostitis, not neuralgia: I do not here attempt to decide.

Rheum of a Sacro-iliac Joint.

This disease is common, and often mistaken as a sacrache, and as indicative of some uterine or ovarian affection. I know it well, for I frequently suffer from it, generally in the right, rarely in the left, less rarely in both. It is a rheumatic ache, sometimes nearly as commanding as a bad lumbago, produced by any bodily movement that causes pressure on or movement of the joint. When a woman has it, she attributes much importance to it, not as a pain, but as an indica-

tion of some latent internal disease of which she has alarm and dread, naturally fostered by ignorance. When she comes to you, you must carefully investigate it, and give her good information and advice.

It is not enough to make out that the region of one or other or of both joints is the seat of pain, for ovarian disease may cause that; nor is it enough, even if, in addition, the pain is aggravated by the erect position or by walking, for that may be also a reflex of ovarian disease. But if, still farther, you find the joint is tender, perhaps a little swollen; and if you find that the least movement of it causes pain, you may be pretty well assured; and you hold the case well ascertained, if you find, on examination of the pelvic excavation, that there is there no disease to account for it. In this affection, your examination discovers ordinary, not surgical, or morbid, mobility of the joint; and when describing looseness of the joint, I told you how to make out its mobility. One source of error in this examination you must note, namely, that the pain is induced by pressure on the anterior iliac spine, and the woman may say the pain is there; but, with care, you make out that the pain is only produced by such pressure on the anterior iliac spine as moves the bone at the sacro-iliac joint, and that pressure on the ilium that does not move the joint is not painful.

Nodes of Connective Tissue.

These are indurated masses, not very hard, irregularly rounded or spindle-shaped, of size varying from that of a bean to that of a hazel nut, generally painless, sometimes tender. There may be only one, or several may be in the same neighbourhood. They have not the characters of neuroma. They may disappear as they come, without known cause.

This disease I have rarely seen, and, as far as I know, it has no direct practical importance, except when the little masses are tender, or when the patient happens to find them, and becomes anxious as to their cause and nature.

We had lately a case in "Martha." The woman had been long in the ward suffering from parametritis and the albuminuria which occasionally accompanies it. She made a good recovery, and, before going away, called attention to little tender lumps. They were three in number; two just above the posterior superior spine of the ilium on the right, and one a little higher on the left.

I have seen a case in which they were situated in the subcutaneous cellular tissue over the sacrum and adjacent part of the hip. In another, the node was the size of a pea, and situated a little above the middle of Poupart's ligament.

Perineal Sweating.

In inveterate cases, however much they may be minor, it is necessary to enter minutely and carefully into every particular, and this is true of none more than that of "whites." A patient will add as a tail to her case that she has whites; or she will say she is cured, all except whites; or she will complain simply of very bad whites. By this she implies that she has a large amount of unhealthy discharge from the vagina, white or nearly white; and this she fears, understanding that it is very dangerous, or at least weakening. Probably also she has used many diverse lotions without avail for a lengthened period.

Now it is common to find that this case has been quite misunderstood, and consequently mismanaged: examination by the speculum discovering no mass of mucus or the matter of whites, no such quantity as would cause discharge. It is indeed not rare, with such complaint, to find the passage drier than natural. Such women it is sufficient to tell that they have no whites, that there is nothing to be cured, that they should give up the use of injections of every kind; and it is good to add that, if all proves not to be right, the patient should return with the whites present, and with the diapers worn, or any evidence of the presence of the disease.

When she comes back, you may find that she has had some whites after a long walk or long standing—a result which is scarcely to be deprecated. Or you may find some superficial irritation of the vestibule or vaginal orifice, from which a white or non-purulent discharge has come, and which may be easily cured by an appropriate application: and the same may be said of some eczema of the pulva. Frequently all she produces is a cloth damp with perineal sweat, and often also stained brown by it. Lately we had in "Martha" an aggravated case of this kind from a distant county. As we could find nothing, the woman was pressed to produce the evidence of her disease for which she had been long treated, and which so alarmed her as to make her glad to encounter the inconvenience and expense of coming to the hospital. She said it came on when walking, and she was accordingly sent to walk; and, with an air of triumph, she then showed a diaper with a small brown stain of feculent odour. The woman was quite simple and ingenuous, and believed that this stain was vaginal whites: it was plainly some brown mucus from the anus.

When women get fat and sweat freely, they often have such moisture about the anus and genitals. This is very disagreeable to them, and, unless correctly instructed regarding it, they are easily induced to believe it is morbid, and the result of vaginal or uterine disease. Both men and women, however careful and cleanly, have their linen moistened and often stained brown, especially if they have walked much; and such discharge a woman is easily led to believe to be whites, and an indication of disease of the womb.

Sudden gushes of watery fluid on the linen are sometimes otherwise explained. Not very long ago a patient consulted me for this, believing that it came from an ovarian cyst, and required constant treatment to prevent the cyst closing. I could find no disease by local examination; but I was also told that when it occurred the patient was very alarmed and nervous, and this led me to suspect it might be urine. The fluid was collected in a cup, and found to have all the qualities of urine. The diagnosis, communicated to the ingenuous patient, that her disease was merely nervous discharge of urine, was enough for her cure, and she went away rejoicing.

But I must further add, that some sudden copious watery discharges I have been quite unable to explain, and have tried to satisfy myself by supposing they were from the glands of Cowper. The neck of the womb may suddenly secrete copiously, but the secretion is very viscid and not in such large quantities, so far as I have observed, as to explain the gushes I am speaking of.

Cases of this kind may be, sometimes, minor examples of hydrops tubæ profluens. This is a disease probably more frequent than is generally supposed, but certainly very rare in its distinct and greater forms. A case lately came under my notice where the gushes of watery and slightly viscid fluid were great, and had a general history as follows: — Gradually increasing hypogastric pain and general constitutional disturbance, then copious flow from vagina and relief for a varying length of time. When the woman was at ease there was to be found only an enlarged uterus: when she was in pain, and before the discharge, there was distinctly connected with the uterus, and lying on its left side, a large and increasing tense and somewhat tender cyst.

Sacrache and Back-ache.

There is no more common, and therefore no more important, symptom of uterine disease, and especially of disease of the neck of the womb, than sacrache. The pain is dull, or an ache rather than pain : it is situated at or near the base of the sacrum ; and, referring to it, the patient puts her hand to the part. I say with emphasis "at or near," and it is desirable to make this more definite. A pain below the middle of the sacrum is not at or near, and a pain above the middle of the lumbar spine is not "at or near." Such pains and aches do not point to the womb as the characteristic sacrache does ; but the characteristic sacrache only points in that direction : it is not, in itself, nearly sufficient, not even strong, evidence of disease of the womb. Occurring in a virgin it would not, alone, unless very severe and inveterate, lead you to make an actual examination of the womb.

Other back aches, that is pains in other regions of the back, not the sacrache, may accompany uterine disease, but do not point to the womb, are not symptoms rationally held as indicating womb disease. Unfortunately women are, at present, so under the influence of bad medical instruction, that they regard all pains in the back, from the occiput to the coccyx, as nearly sure indication of uterine mischief, and demanding uterine treatment.

The sacrache of womb disease may be constant, but generally it comes and goes. Frequently it is dispelled by lying, is felt on going to bed, and has disappeared before morning, and long standing makes it reach its highest pitch. When it is otherwise, that is when the ache is worse in the morning before getting out of bed, or is relieved by walking, then it is certainly not uterine.

I have said that you must not regard all sacraches or other back aches as uterine. They are common in men and in women. A weakly woman, who attends to all her pains, can do no standing or walking without back ache, and often it is a sacrache ; especially, if she has a long back, will she suffer in this way.

The pains liable to be confused with real sacrache are all in the lower back, about the lumbar spine : it is only such that might mislead any rational physician. Regarding them you will get some light from noticing the causes of the same pains in men. Now I find that weakly men are liable to these aches, sacral or lumbar, on walking or standing ; and in many they are produced by excessive venereal indulgence.

ON THE CONSTANCY OF OUTBREAKS OF MALARIAL FEVER UPON DISTURBANCE OF THE SITES OF OLD CITIES.[1]

By EDWARD ATKINSON, M.R.C.S, F.L.S.,

Surgeon to the Leeds General Infirmary, Lecturer on Surgery at the Leeds School of Medicine, &c., &c.

For many years past it has struck me that the revived interest in the exploration of ancient sites, which in our generation has been so remarkable, whilst it has given rise to numberless theories and speculations of an antiquarian kind—to be confirmed or refuted, more or less, by excavations on the spot—has at any rate been the means, as often as such excavations have been made, of bringing to light one fact which was not anticipated.

In all the great centres of civilization, no matter what the physical character of the site, as to elevation or geological formation, so soon as pick and shovel have been set to work, one uniform result has happened—viz., the occurence of malarial fever amongst those employed. Sometimes the cases have been few and scattered ; sometimes the outbreak has been general, and shared not only by the excavators but by the surrounding population—has become epidemic in fact. Sometimes the fever has been in the form of an ordinary intermittent ague, which slowly but surely deteriorated the powers of its victims, and from which the only escape, though kept under for a time by constant doses of quinine, was a change of climate. Sometimes, however, the attack has been of so malignant a type as to kill quickly and certainly. Not a few valuable lives have been sacrificed in this way to their devotion to archæology.

My object on this occasion is merely to bring together a few well-attested instances of this apparent connection between the breaking of ground, occupied long centuries ago by dense populations, and the immediate occurrence of fever. Secondly, to point out the diversity of the sites on which the same results have followed. And, thirdly, to offer an explanation, however crude, of the phenomenon.

I.—Among the homes of malaria there are few more notorious than Rome. Here malarial fever may be said to be endemic throughout the year, though most prevalent from July to October. This has been generally referred to the emanations from the marshes of the Campagna ; and the well-known "stinking fogs" which prevail in the autumn are supposed, I believe, to owe their malignant breath to the effects of the first rains which fall on decayed vegetable soil, after the long drought of summer. But when we reflect that Rome has been continuously inhabited for over twenty-six centuries, and that the population, which now numbers only 300,000 (and which on the entry of the Italians in 1870 was only 220,000), was in the days of Claudius Cæsar (*i.e.*, including the suburbs) nearly, if not quite equal, to that of modern London—being stated by Livy at 3,968,000,—we can readily imagine to how great an extent the present soil of the city consists of animal matter. There are now large tracts of ground within the walls unoccupied, which were formerly covered densely with dwellings. Wherever this ground is broken for the erection of new buildings—as when a few years ago, on the accession of the new regime, a whole quarter, which had lain desolate for centuries, was laid out in new streets and boulevards—fresh outbreaks of malarial fever are sure to occur ; and this was abundantly noted by newspaper correspondents at the time. When, some years previously. the Forum was excavated for the purpose of archæological research, the same fact was observed. And when I was in Rome at the end of May, 1856, there was much fever prevailing, and people looked forward with apprehension to its type becoming more severe as the year advanced.

At Naples, I believe, identical conditions are observed, but as that city is more stationary, fewer opportunities arise for disturbing old sites. While, on the opposite side of the bay, the extensive excavations at Pompeii have been but little interrupted by fever—and this I interpret as a direct confirmation of my theory ; for the manner of its destruction, together with a large proportion of its inhabitants, was practically a holocaust, or wholesale cremation.

If we now travel Eastwards, we gather similar evidence from all the explorers, as well as residents among the ancient cities of the Levant.

Athens, Corinth, Constantinople, Tarsus, Smyrna, all yield testimony to the coincidence. It is true that in all these places fever of a malarial type is endemic ; but in the last-named city, where I lived for fifteen months, I had an opportunity of personally observing the fresh outbreak of a severer form in connection with

[1] Read before a recent meeting of the Leeds Priestley Club.

digging the foundations of a new synagogue in the oldest part of the town.

Ephesus is a notorious fever nest, and indeed no one can now live there. Its modern representative, Ayasaluk, a miserable hamlet two miles off, though having a somewhat more elevated situation, has not a single healthy-looking inhabitant. But Mr. Wood, who so laboriously and successfully excavated on the old site, in search of the Temple of Diana, abundantly testifies to the difficulties he and his workmen encountered from malarial exhalations on the site which, 1,600 years ago, supported a busy and energetic population of many thousands.

Again, in the Troad, we learn the same from Dr. Schliemann, when working at his excavations on the top of the hill of Hissarlik, with 120 men. He has reached a depth of thirty feet through the dry *debris* of three or four successive cities, when he exclaims: "I will not say anything about our mode of life here, where everything is wanting, and where we have to take four grains of quinine every morning as a precaution against the pestilential malaria." Further on, writing in November, 1871, he says: "The constant warm damp weather produces a very malignant fever, and my services as a doctor are daily sought—fortunately I have a large stock of quinine, and can thus help everyone. . . . . I generally give four doses of sixteen grains. Thus far I have cured all who applied; not one, however, has ever come to thank me—indeed, gratitude does not appear to be one of the virtues of modern Trojans!"

During my own residence of four years in Jerusalem, *before* the Palestine Exploration Society commenced its operations, I had especial opportunities for comparing the ordinary endemic intermittent—which constituted by far the largest proportion of all the cases of illness that came under my care—with the severer and often more fatal form of fever which occurred from time to time in connection with the digging foundations within the walls. The city is said to have been rebuilt seven times on the same site, and the consequent accumulations of *debris* are enormous in depth, varying from 30 or 40 feet on the hills, to 120 or more in the valleys which intersect them. Whenever old rock-cisterns, which have been used for the storage of rain water from time immemorial in Jerusalem, and many of which have been buried and unused beneath ruined houses for centuries—whenever these were uncovered and cleared out for use, or whenever excavations had to be made down to the rock for laying foundations (as in the case of the large new Austrian Hospice, built in 1858-59), the type of fever excited among those employed, especially if they were not natives, and sometimes among the surrounding population, was far worse than the ordinary run of cases. For seven months in the year, from the beginning of April till about the 20th October, *no* rain falls, and there is a complete absence of running or standing water (excepting two closed "pools" or tanks) either in the city or its neighbourhood, so that the soil consisting of old *debris* is perfectly dry, and when a pit or shaft is sunk, the sides *run like water* from mere want of cohesion. In these excavations, for some time after their first exposure, I have often noticed a peculiar sickly odour, unlike anything else—but the very recollection of it vividly recalls the sensation to my imagination.

Captain Conder, R.E., in recording the death of Mr. Tyrwhitt Drake in Jerusalem, in June, 1874, says: "The death of Drake adds one more to the list of those who have fallen in harness in the exploration of Palestine. The fatal Jordan Valley climate took one member from Lieut. Lynch's party. Dr. Tristram's expedition did not escape a similar calamity. The exploration of Jerusalem cost the life of one of Captain Warren's men, and the health of another. We had trusted that in the serious illness which obliged Captain Stewart to resign the command of the survey, our debt to the country was paid . . . . . but it was not to be so."

The reference to the deadly climate of the Jordan Valley, induces me to remark, that although the climatic conditions are the very opposite to those of the dry and lofty site of Jerusalem, yet there is much more than the deeply depressed valley, the luxuriant vegetation, and steamy atmosphere to account for its fatal reputation; as for many centuries the whole plain was dotted over with towns, and supported a dense population.

In his account of his lengthened operations at Nimroud and Kouyunjik (the site of ancient Nineveh), Layard does not lay stress on the occurrence of fever as a result, though his casual references are enough to show that he and his men did not escape its effects.

Canon Tristram writes me: "At Carthage, directly they began to excavate in 1857, fever of the malarial type broke out, though absolutely unknown there before. In Algeria this has been," he says, "most remarkable. Everywhere, on re-colonizing an old site, though desolate for 1,500 years, deadly fever has broken out, even in the driest situations. I am not aware that it ever appeared on *new* and virgin localities. For example, in the Plain of the Metidjeh, behind Algiers, a plain quite dry and overrun with the dwarf palm, the French, soon after the capture, settled Buffarieh on an old Roman site, and about 1840 also Blidah, another Roman town. The Metidjeh was healthy elsewhere, but in these two places the fever was most malignant. Convicts were employed to clear and cultivate Blidah, and it was said the population was thrice buried in three years! The fever continued for about four years longer, but cultivation was persevered in, and now for many years past the orange-girt town of Blidah has been the sanatorium of Algeria, and fever unknown. The same thing occurred at Thebeste, the ancient *Thogastum*, in Eastern Algeria, and at Lambessa. In fact I know of no case in North Africa where re-occupation has not evoked malarial fever, unknown until the soil was upturned—and this quite irrespective of wet or dry; sand, clay or rock. It surely must be that the mass of decayed matter, accumulated where man resides for long, needs to be constantly in contact with the atmosphere, in order to neutralize its poison; and that it retains its noxious properties when buried in the earth for an unlimited period."

II. The great diversity of the sites which I have referred to, whether regard be had to their elevation—their geological features—their proximity to, or distance from the sea—their moisture or dryness—their alternations of seasons, or more uniform sub-tropical climate—their abundance of vegetation, or almost absolute sterilty—must, I think, lead to the conclusion that the physical conditions of the localities have little to do with the production of the poison—call it "malaria," or what else we choose—which causes these outbreaks of fever whenever the soil is disturbed for the first time on the sites of dense old-world populations.

Rome, with its great river rolling through its midst, and surrounded by the level alluvial expanse of the Campagna; Carthage, on its gently sloping limestone situation, a few miles from the sea; Troy, Corinth, and Athens, all standing more or less on hills, though with plains around; Constantinople, rising from the shores of the Bosphorus, but with no large fresh-water stream near it, and not any excess of vegetation in its neighbourhood; Jerusalem, standing on a plateau of dry mountain limestone, 2,500 feet above the sea; Jericho, in a valley watered by many streams, and at a depth of 700 ft. below the sea level, with luxuriant vegetation around; the mounds of Nimroud and Babylon on the banks of the Tigris, with a broad expanse of hot alluvial plains, partially cultivated, but almost treeless;

*

all agree in this—that malarial fever, whether it be endemic or not, is sure to attack those who break through the old crust which covers the remains of the past.

III. It would be out of place for me to discuss here the various theories which have been advanced since the days of Lancisi, of Rome ("De noxiis paludum effluviis," 1695), down to Sir Joseph Fayrer, who, in the spring of last year, gave an exhaustive account of "The Climate and Fevers of India," in his Croonian Lectures before the Royal College of Physicians, and reviewed therein the explanations of the origin of malaria, offered by a host of writers during the last two centuries.

The generally received theory was, that where there is much heat and moisture we usually find much and rank vegetation, and much vegetable dissolution and decay. "Therefore," says Sir Thomas Watson, "the belief was as natural as it was general, that the putrefaction of vegetable matter was somehow or other requisite to the formation of the poison that exists so commonly in swampy situations. Yet very strong facts have been adduced to show that vegetable decomposition is only an accidental accompaniment of the miasm, and not by any means an essential condition of its evolution. Decomposition of vegetable matter goes on," he says, "abundantly in hot weather without producing malaria—witness the rotting cabbage-leaves in Covent Garden, or the neglected dust-bins of London (1843); or the putrefying and offensive heaps of seaweed on our healthiest coasts." But to show the converse, he quotes Dr. Ferguson, whose experience was gathered in Spain during the Peninsular War, and who shows that the peculiar poison of malaria may abound where there is no vegetable matter to decay. He then proceeds to combat the theory of putrefying animal matter being a necessary element in the production of malaria, by pointing out that a similar argument might apply to it also in many cases. He even goes so far as to say, "I hope to prove that neither animal nor vegetable decomposition is sufficient to generate fever of any kind!"

With regard, however, to the specific form—for I believe it should be deemed so—in which the elements of malaria exist in the soil of old inhabited sites, and where its development depends not so much on the *drying up* of the soil after rain (as is so undoubtedly true of many situations where the poison is traceable to comparatively recent conditions), as to its being *disturbed*—dug up and exposed for the first time to the air. With regard to this peculiarly malignant malaria of ancient sites, I believe it is due to the saturation of the soil with animal matter and animal secretions in a semi-fossil condition, so to speak. That whether or not there be any organic germs which can preserve their vitality for an indefinite period, when buried—and whether or not such germs, if they exist, owe their preservation to the abundant presence of nitrites, which become resolved or oxydised (and converted into nitrates) by exposure to the air; there must be a vast accumulation of nitrogenous compounds which have never been washed out by the rains, but which have lain festering for centuries, ready to work mischief to whoever stirred them up.

Since reading the above paper, I have been in correspondence with Dr. Lauchlan Aitken, of Rome, who has very kindly afforded me the following valuable information in corroboration of my statements:—

He writes . . . . "Before giving you details of the outbreak I refer to, I may mention that in all the excavating and digging required for the foundations of new houses, for the laying down of drains, or for the formation of streets, in parts of the city long unbuilt on, there are invariably cases of malarial fever among the workmen, and that not only in the summer and autumn, but also in the winter and spring, though the severity of the attacks depends very much upon the season of the year and climatal conditions existing. When the houses are finished, the streets paved, and the drains in action, these cases cease to occur. Any Government or municipal excavations going on, therefore, on a large scale, are restricted to the period from November to June; and in this way the number of severe cases thus originating remains very limited.

"The present excavations beside the Forum and just under the Palatine Hill are an instance in point—the workmen scarcely suffering at all, as they were only begun in November; and yet these are in soil probably untouched since the ninth century. A young Englishman, whom I saw the other day, got a slight intermittent attack from standing watching the digging going on . . . . . In 1874, when the excavations for the laying bare of the substructures and true area of the Colosseum were in progress, an English officer, who was watching the work one damp afternoon in January, got a very bad attack of malarial fever, which I could not trace to any other source; and I might tell you of many similar cases.

"But the epidemic outbreak of malarial fever to which I referred at the beginning of this letter, occurred in the summer and autumn of 1879, and was due to the works for the embankment of the Tiber. The excavations on the right bank of the river, just above the Ponte Sisto, and behind the Farnesina Palace, had been actively prosecuted for some time, when they were suddenly brought to a standstill by the opposition of the proprietor of that historic palace—a Spanish grandee—who maintained that the operations were endangering the building, and more especially the well-known frescoes of the Cupid and Psyche, and of the Galatea of Raphael. While the matter was before the law courts, all work was suspended, and a large extent of newly excavated soil was for long exposed to the air, rain, and sun. Numerous pools of water formed in pits and became rapidly covered with algæ. The season happened to be particularly favourable to the development of the germs of malaria (as was shown by the occurrence of fevers of this type at Rocca di Papa, a village on the slope of the Alban Hills, some 2,600 feet above the level of the sea, and where it is very unusual to see cases originate). The result was a great outbreak of fever of a very severe type, as early as July, in those districts of the Trastevere lying nearest to the Farnesina Palace. So alarming was the outbreak, and so rapidly did the number of cases increase, that the municipality, along with the prefect of the city, and the minister of public works, had to adopt very active measures. Several medical men were appointed temporarily for the district, and medicines, especially quinine, liberally supplied. The excavations were stopped for the time, any pits filled up, and large quantities of lime thrown in. The outbreak gradually diminished in intensity, and with the advent of winter disappeared; though the recurrence of some fatal cases in the following March renewed the alarm to some extent. Since that time no excavations for the Tiber Embankment have been permitted between June and November, and the works have been under constant sanitary inspection. A physician appointed by the municipality visits them daily, and when he finds any drainage or filling-up of pits required, or considers that freshly turned-up soil should be removed and lime thrown down, his orders must be obeyed. These precautions have had the desired effect, and no further outbreak of fever attributable to these works has been seen since 1879.

"Although the exact number of deaths directly

traced to this cause is unknown, yet it was probably considerable, as the following figures show :—

In 1877 there were	326	deaths from malarial fevers.	
In 1878	„ 294	„	„
In 1879	„ 481	„	„
In 1882	„ 298	„	„
In 1883 { First 8 months }	232	„	„

"My figures for 1880 and 1881 are incomplete."

These remarks of Dr. Aitken, under date of Rome, Dec. 3rd, 1883, form a most interesting appendix to the materials I had previously collected.

PRACTICAL NOTES ON THE ORDINARY DISEASES OF INDIA, ESPECIALLY THOSE PREVALENT IN BENGAL.

By NORMAN CHEVERS, C.I.E., M.D.,
President of the Epidemiological Society of London.

(*Continued from page* 683 *of Vol. II. of* 1883.)

DISEASED CONDITIONS CONSEQUENT UPON MALARIAL CACHEXIA—*continued.*

Two of the most important developments of Malarious Cachexia are neuroses—*Neuralgia* and *Asthma*.

Malarious Neuralgia, in its various forms—*Facial* and *Hemicranial, Brow Ague* and *Intermittent Headache*—and neuralgic affections of other nerves, as the *Sciatic, Spermatic*[1], &c., are, with the exception of the last, much severer and far more prevalent results of malarial poisoning in England than they are in India. Although, in that country, we see neuralgia march side by side with paludal fever, this neurosis appears to be the special congener of those fevers of which strong ague is a marked characteristic.

Two singular forms of malarial neuralgia are, however, frequent in our Eastern possessions—*Burning of the Feet* and *Neuralgia of the Shins.*

The former affection was the subject of monographs by Drs. Grierson,[2] Malcolmson,[3] McKenna,[4] and Waring.[5]

It is, according to Waring, most prevalent in Arracan, Burmah, the Tenasserim Provinces, Penang, Singapore, and our other Eastern Settlements, less so on the continent of India, although it occurs there in the hospitals of native regiments. I never saw or heard of but one case in Lower Bengal. The patient was a fine-looking but rather thin Sepoy, who was sent from Fort William to be placed in my ward for observation. A high official came, inspected him with me, and asked my opinion. The man sat on his bed with his feet on a pillow, the soles being turned inward, so as to face one another for protection. The attacks were paroxysmal, and the soles could not even bear the contact of a sheet. I said that I considered it to be a case of Burning of the Feet, as described by Malcolmson. The reply was, "I never heard of Malcolmson, or of Burning of the Feet; I think that he is malingering!" A young medical officer, recently from Netley, who stood by, said, "I have read Malcolmson on Burning of the Feet." I added, "He is certainly not malingering; look at his agonised features and the beads of sweat on his forehead." I employed quinine and all other feasible means, but could do little for the poor fellow's relief. Grierson and Waring attribute this disease mainly to malarious influence. Mr. Playfair,[6] describes two forms of this disease as being commonly met with, both in the feet and hands—(1) in which the parts affected are in a constant state of moisture, from sudor; (2) the other, in which the extremities are dry, and sometimes scaly: but there are several varieties. In some, the feet only are affected; in others, the hands; in many, both hands and feet. In a few, the feet are dry, while the hands are bathed in sweat; but, in all, the disease is very distressing, generally preventing all natural rest, and disordering the animal functions in a remarkable degree. The patients describe their sufferings as nearly insupportable. Waring remarks upon the difficulty which has always been experienced in curing this disease. He considers that, as dyspepsia, with light clay-coloured yeasty stools, appears to exist in the majority of cases, our first endeavour should be directed towards establishing a healthy condition of the assimilative functions. Dr. McKenna relied much upon the liquor arsenicalis, in four-drop doses, and iron and quinine, where the exacerbations are distinct. As local applications, the leaves of *Mhíndí* (*Lawsonia alba*), strong solutions of opium and iodine, and aconitine ointment, are recommended by Waring, who, however, insists upon early removal of the patient to his native place. The detention of Sepoys in the Eastern Settlements often proved fatal.

Many ill-fed Bengalees suffer greatly from *Neuralgic Pains in the Shins*, which has been recognised as a disorder allied to Burning of the Feet. The patient sits, with a deplorable aspect, on his bed, with his knees bent up, and his feet flat and drawn under him, "hunkering" in the usual native manner; but he holds his hands protectingly on either side of his shins, with the fingers turned inwards, suggesting the notion that his tibiæ are musical instruments, the keys of which he would touch delicately, if they were not too sensitive. At my first station, one of my earliest patients was a prisoner in the jail hospital thus afflicted. Considering that the pain was rheumatic, I gave vinum colchici. In a short time, diarrhœa set in, then both corneæ sloughed. My compunction was extreme; and I fear that my sense of relief amounted to satisfaction, when, in a day or two, other patients, who had not taken colchicum, got sloughing of the corneæ. Gout not being prevalent in India, I have never prescribed colchicum since.

Dr. Morehead has a very interesting note (page 654) on *Paroxysmal Headache;* cases of *Hemicrania, Intermittent Cephalalgia*, and moderate *Brow Ague*, generally yield without any great obstinacy to quinine in Bengal.

I have not seen a great deal of *Migraine*, but, in Bengal, especially among men who overwork their brains, it is well marked, and is inclined to display periodicity. In one case it came every Thursday—this was not my case—but quinine did not appear to touch it. I saw cases of *Facial Neuralgia* distinctly marked, but few. My father, a naval surgeon, was, I believe, one of the first, probably the very first, who recommended large doses of quinine in facial neuralgia; and I consider it due to his memory to give a brief record of the facts. About the year 1810, he had charge of a French prison hospital ship moored near a salt marsh at Plymouth. His duty occasioned him extreme anxiety and vexation, and there he had his first attack of *tic*. His second attack was at Greenhithe, in the Kentish marshes, in 1823. Although I was a very young child, I have a vivid recollection of the strong man's almost intolerable agony. With desperate firmness he swallowed large quantities of cinchona powder, and got over the attack in a few days, but remained in broken health for months.[7] His

[1] Here pain usually depends on local organic changes—as in elephantoid disease.

[7] I do not know whether it was he who met with the case of a poor woman, living in an English marsh, in whom the pain was so excessive for years that there was a hole in her cheek, through which the teeth were visible. Probably there was cancrum oris.

third and last attack (he died in 1847) was at Portsea—also then a malarious place—about the year 1831. This was a very severe attack. He then took quinine, I think in six-grain doses, repeated frequently, as the suffering compelled him. The cure was speedy. He, of course, spoke freely of his success to his brother officers, and, among others, to Dr. ——, a naval surgeon of considerable scientific acquirements. Some time afterwards, Dr. ——, being in a ship on the Irish station, heard that the Marquis of Anglesea was a martyr to facial neuralgia. He obtained an introduction, and was allowed to make trial of quinine. Either by a fortunate accident, or because the drug had temporary power as a nervine tonic, the effect appeared to be marvellous, and the Lord-Lieutenant knighted Dr.—— and settled upon him a very handsome life annuity. The disease, however, appears to have been reflex in this case, being attributed to the condition of the nerves in the stump of the leg which his lordship lost at Waterloo. In that and in other traumatic non-malarious cases of neuralgia, quinine entirely failed.

In very malarious places in India, as at Chittagong, ganglia, of no extreme sensitiveness, are apt to form temporarily in the course of nerves. In one of these cases a lash of cutaneous nerves, on the inside of the arm of a lady who had suffered much from repeated attacks of intermittent fever, was visibly enlarged with little spindle-shaped ganglia in the course of each nerve, after the manner of a branch of *fucus vesiculosus*. This condition disappeared after some years. In another very remarkable case which my friend, the late Dr. Allen Webb, showed me, there was a much larger ganglion, apparently of this kind, on the pneumogastric trunk on one side of the neck of a jewess in Calcutta. I have never seen a surgeon who had more complete use of his hands than Dr. Webb had, and he showed me that, by pressing this ganglion—not the common carotid — he could immediately render the woman insensible. The nerve and ganglion were not painful.

Malarious Spasmodic Asthma. — Dr. John Quincy noticed the occurrence of asthma, as a sequel of intermittent fever, in 1728.[8] Copland[9] speaks of asthma as appearing as a masked form of intermittent. "Malaria," says Dr. Theodore Williams,[10] "plays an important part occasionally in the causation of asthma." Early in its English history, Bengal became notorious for asthma. It is singular that this fact was the origin of the great Lord Clive's success in life. General Arthur Broome tells us,[11] that when, in consequence of the events which led to the catastrophe of the "Black Hole," a relieving force was ordered to proceed from Madras to Calcutta, in 1756, "the gallant Colonel Stringer Lawrence, who commanded the Company's force on the coast, was severely afflicted with asthma, to which it was feared that the fog and damps of Bengal would prove so adverse, as probably to incapacitate him from active duty. Under these circumstances, Colonel Robert Clive, the second in command of the Company's troops, was selected for this important charge."

Malarious asthma has been observed elsewhere in India. Dr. Morehead gives the following case—that of a Hindoo drummer, æt. 30, who had suffered for about eight months from intermittent fever and asthma, which was liable to return at intervals of 15 days. Emphysema was present. The paroxysms of fever and of dyspnœa increased together at night, and ceased towards morning. The asthma and fever ceased in three days, under the use of quinine in four-grain doses, with sulphate of iron and rubefacients to the chest. Dr. Morehead remarks, "This case is interesting from its bearing on the therapeutic fact that some cases of spasmodic asthma in India are most successfully treated with quinine and small doses of sulphate of iron during the absence of the paroxysm, and in these cases it is reasonable to infer that the asthmatic symptoms have been related to malaria as a cause. To determine the probability of a previous malarious influence, by enquiry into the history of the case, and the condition of the spleen, constitutes an important part of the examination of asthmatic patients in India. If there be good reason for suspecting it, quinine and iron are indicated, and a more favourable prognosis than in asthma under other circumstances, provided the emphysema is not great, may be entertained."

The following is another Bombay case by Dr. Murray:[12] "An officer, 12 years in India, who has for the last ten years suffered from asthma, fever, and other diseases, arrived here" (Mahabableshwar Convalescent Hill Station) "in the middle of April, having had ague on the journey; his principal complaint, however, was the difficulty in breathing, which for a long time used to affect him, chiefly at night (having all the characters of a regular fit of asthma, and rendering him totally unfit for duty on the following day), but latterly these attacks had continued throughout the day. With scarcely any medical treatment, this officer continued almost entirely free from asthma during a two months' residence here; having had only two slight paroxysms during the six weeks preceding his departure."

In Bengal I saw many cases in Europeans—five in medical officers of the Bengal Service, and one in a Madras medical officer. I only recollect two in natives —of European habits. Dr. Morehead says, that "It is sufficiently common in natives of India, more particularly in the cold and wet seasons of the year."

In nearly all the cases that I have seen or heard of, the disease has been contracted *in paludal situations, within the influence of the sea breeze.* In this respect, it therefore appears to march with elephantoid fever, which has never been known to originate beyond the habitat of the cocoa-nut tree. So much did I mistrust the influence of the sea margin, that about two years ago I endeavoured to persuade a brother officer, who still suffers occasionally from Bengal asthma, to seek change in a dry spot inland. He, however, went to the Undercliff. He arrived well, but after a walk over broken ground had a very severe attack; after this, while I felt that I had not quite sufficient facts to prove that the sea-side is not an eligible residence for the subjects of this neurosis, I had the privilege of mentioning my strong suspicion to Dr. E. Headlam Greenhow, who informed me that large experience has convinced him that many asthmatics are made worse by a residence at the sea-side. Dr. Greenhow has known many who, after escaping an attack of spasmodic asthma for long intervals, invariably had a paroxysm on going to the coast, even for a brief visit. This, he added, is not absolutely universal, for he has met with a *very* few exceptional cases. These exceptions may, I think, be due to the law that spasmodic asthma only attacks us *at its own time.* Thus, after I had got over an attack in India, I never feared that any circumstance would again call up the disease for months to come.

Then I have before me the facts that the friend to whose case I have alluded above urged upon me that, when at sea, he has always been free from asthma, and that I, in five voyages to and from India, never experienced the slightest symptoms of the disease. I am therefore induced to inquire whether, this disease being essentially paludal, and a large proportion of sea-side places having salt marshes in their vicinity, it is not probable that it is *salt marsh* air, not pure *sea*

air, which has caused such great affliction to many of us.

Considerable as the bulk of our medical literature on watering-places at present is, there appears to be room for a slender tract on the advantages of those few sea-side resorts which are free from marshiness. To seek refreshment in a swamp at the hottest season is rather the act of a buffalo or a wild pig than that of a circumspect, well-advised paterfamilias, who desires to afford the blessings of ozone and sea-water to his etiolated flock. It would be well, therefore, to guide public instinct in the right direction. I shall be grateful for notes on sea-side places which afford relief to the victims of neurotic asthma, and on British and other European watering-places which are free from marsh.

I am acquainted with the case of an aged lady who, residing near land reclaimed from the sea, was asthmatic for many years. Removing to a drier locality on the same coast, she has been wholly relieved.

As I have already mentioned, I became the subject of spasmodic asthma at Chittagong, a very marshy sea-side place, after I had begun to suffer from the most tenacious intermittent fever for which that spot is notorious. In the twenty-five cold seasons which I spent in India, I suffered from asthma in twenty-four. I was not constantly asthmatic, but I always expected to be attacked at the setting-in of the cold weather. Of late years, the dyspnœa was not extremely severe, but the attacks were more protracted than formerly, sometimes extending to six weeks, spasms giving way to bronchitis. In the first twelve years, I believe that I was repeatedly upon the point of death by suffocation. I felt convinced that I was becoming asphyxiated; and that spasm only relaxed when I was beginning to die from exhausted innervation. In ordinary attacks the dyspnœa was endurable as long as I was able to sit still. Returning to England after eighteen years' service, I spent eighteen months at Cheltenham, where I had a most violent attack of tertian ague and a severe attack of bronchitis, *but not the very slightest symptom of spasmodic asthma.* On returning to Bengal, I again became subject to asthma. In 1872 I came home, and resided for eighteen months in Bayswater, enjoying good health, *and not having a symptom of asthma*, except a vague threatening while staying at a malarious watering-place. The disease recurred on my return to Calcutta. I have now resided in retirement in Bayswater for nearly eight years. I have had more than one severe attack of bronchitis, and have experienced threatenings of intermittent fever; but *there has been no sign of asthma*, save an indefinite sense of chest uneasiness once at another watering-place, which, if not built upon a marsh, has extensive marshes on either side of it. I now avoid the sea-side. I do not in the least dread the atmosphere of the underground railway, and I do not think that a London fog distresses me more than it does other persons of my age.

In many Indian cases the amount of spasm is terrible. I was called in the middle of the day to see a youngish man, of European parents, born in Bengal, in one of my colleague's wards. He had all the appearance of being on the verge of suffocation. His epigastrium was tucked in, almost to his spine, by fixed spasmodic contraction of the diaphragm, and there was so much laryngismus that, for many minutes, I had thoughts of opening his trachea. I afterwards found that he was a very nervous, hysterical subject.

In my own and several other cases which I have seen, a few days' asthma leads to profuse bronchorrhœa, attended with great shortness of breath on exertion, which may continue for weeks.

Treatment.—My own case resisted quinine and most other reputed specifics. In the intervals I took long courses of quinine as a nervine tonic. My brother-officer, whose attacks were markedly periodic, was benefited by quinine. Alcohol was hurtful in my case, and gave me no satisfaction in treating others. When I went to Calcutta I obtained a fresh stramonium plant, about four feet high and bushy in proportion. As, in course of years, I smoked the whole of this—leaves, fruit and stem—it probably did me good; but the relief which stramonium-smoking gave me was not very considerable. Latterly, I used the English and French cigarettes. Touch-paper and sips of very hot unsweetened coffee gave some little relief. At first, being as much emaciated as an otherwise active man could well be, I starved, restricting my allowance of fluids and solids to the very utmost. Latterly, I took my usual diet, I think, with advantage. When ill, all acids, vegetable and mineral, made me worse. I believe that other Bengal asthmatics have been as fortunate as myself in escaping asthma on their return to England. In my own person, I have noticed a peculiarity which I have observed in three other cases—that the right lung is distinctly more troubled than the left, as if the liver and right phrenic nerve were participants in the neurosis.

In my own case, violent and continued morning attacks of sneezing, with profuse lacrimation, seemed to be an alternative of asthma.

Seeing that my own case covers thirty-three years, I do not think that, even when most obstinate, this neurosis greatly, or at least immediately, endangers the integrity of the heart and air-cells. But this, of course, depends much upon constitution and mode of life. The native brother-officer, of whom I have spoken, was considered, while in India, to have dilatation of the right heart. He came to England and succumbed more readily than he would probably have done otherwise to an attack of what it is now the fashion to term "pulmonary congestion," which I can only recognise as the first stage of double pneumonia.

Malarial Cardiac Asthenia.—This appropriate designation has been given by Sir Joseph Fayrer[13] to a state of the heart which is rather frequent among Europeans in Lower Bengal. Recognising the fact that malarious cachexia weakens muscular power generally, and especially tells upon the contractile force of the heart, and that chronic asthma tends to dilate the right heart, it might be supposed that cardiac asthenia would be a frequent attendant of malarial asthma; but this does not generally occur. A. has greatly deranged action of the heart, perhaps with habitual shortness of breath, but without spasmodic asthma; B. has asthma without cardiac distress. In fact these are separate neuroses which we do not expect to meet with in the same individual. The ordinary history of a case of cardiac asthenia is as follows:—

A European, who has been long resident in a malarious Indian locality, and who is anæmic, becomes the subject of præcordial uneasiness, This may be very slight, little more than a sense of "fluttering," or it may be so severe as almost to amount to angina pectoris. In aggravated cases, the patient starts up suddenly, just as he has fallen into his first sleep, with a sense of grave cardiac distress. In advanced cases, the cardiac muscular tissue having become weakened, there is functional dilatation (stretching) of the organ, as evidenced by increased area of præcordial dulness. There is generally shortness of breath in these and other cases of paludal anæmia. An irregular and intermitting pulse is characteristic of this form of cardiac asthenia. Seventeen years ago, I was myself the subject of a temporary disorder which appeared to throw considerable light upon the nature of this condition of the heart. In very pleasant, cool weather, I started

[13] "Croonian Lectures," p. 183.

with two brother officers from Gowhatte, in Assam, for Shillong in the Kasia Hills. I was in remarkably good health; we had ponies, and the trip was full of interest. After two or three days my pony broke down, and none of the others being equal to my weight, I had to walk. I was never in the habit of walking far, and had walked very little for many years. I now walked further, generally up hill, than I had ever done even in my youth. My heart's action has always been very quiet—almost to weakness. I now found that my pulse was very intermittent. I perceived that this unwonted exercise had stretched the heart's chambers, and it became a question—is this dilatation to be permanent? This was answered when I found that the pulse improved daily, became regular in less than a week, and remained so. Had I been a smoker, I should have anticipated this occurrence, as tobacco-smoking was evidently a powerful concurrent cause in many of the numerous cases of malarial cardiac asthenia which came under my observation. But, undoubtedly, this form of cardiac debility occurs in ladies, and in men who are not smokers. In all these cases I gave quinine and iron, and urged return to Europe for many months. In uncomplicated cases, when these measures are adopted early, recovery may, I think, always be predicated. I treated one of my worst cases, an eminent missionary, in 1856. He returned to Scotland in the following year, and has ever since pursued a very active career at home. When I saw him a few months ago, he appeared to be a perfectly healthy man of 66.

I do not think that *Hay Fever* occurs in India. I lately met an officer who suffered from this malady before he went to India, and lost it there. And I have seen more than one person who was violently attacked on returning from India.

(*To be continued.*)

NOTE ON THE TREATMENT OF SPINAL CARIES BY OPERATION.

By RICHARD DAVY, F.R.C.S.
Surgeon to the Westminster Hospital.

I HAVE read Mr. Treves' paper on "The Direct Treatment of Spinal Caries by Operation," brought before the Royal Medical and Chirurgical Society of London, and can endorse his views to a practical extent, as evidenced by my own practice. From my own surgical experience, and from facts observed at the mortuary, I have learnt to view with slight favour the opening of abscesses in connection with vertebral disease, and have taught that, as a rule, any such interference is fraught with inconveniences both to the patient and surgeon.

A man, æt. 38, was admitted into the Westminster Hospital in May, 1879, suffering from diseased lumbar vertebræ with deformity, associated with a large psoas abscess, which had burst below Poupart's ligament on the right thigh. I wished to ascertain, by making a dependent opening in his loin, if good drainage might not assist in promoting a cure.

On May 29th, 1879, having had a silver probe specially made, 20 inches long, I passed it through the abscess opening in Scarpa's triangle, along the sheath of the psoas muscle, towards the right loin with care; and without any difficulty I could feel exposed bone. Having withdrawn the probe, and made a short bend at its point (45°), I reintroduced it along the psoas sheath, until it touched the top of the abscess-wall, directing the point of the probe towards the loin. I then cut down on it, introduced my forefinger through the lumbar wound into the abscess sac; felt the denuded bone, and washed out the detritus with a stream of warm water through the tunnel from the right groin to the loin. The lumbar wound was maintained open by a drainage anchor. The patient was discharged with both wounds healed; but the old abscess-opening in the groin seemed inclined to re-open on his assuming the erect posture. When compulsorily pressed to open a psoas abscess, I have always chosen the loin as a point of selection; being unable to see why a lumbar abscess should have the honour of exemption from ordinary surgical custom; viz., a large dependent opening for the promotion of cleanliness and good drainage.

REPORTS OF

HOSPITAL PRACTICE IN MEDICINE AND SURGERY.

GUY'S HOSPITAL.

CASE OF ACUTE DIABETES.

(Under the care of Dr. WILKS, F.R.S.)

(Reported by W. S. AUDLAND, M.R.C.S., Eng., L.R.C.P., Lon.)

THOS. O'L., æt. 23, was admitted into John Ward on October 31st, 1883, for glycosuria. Patient was a clerk, but for the last year has been out of work, and so has been living very badly.

Family history and personal medical history both good.

About a fortnight ago patient began to feel weak, and suffered from much lassitude, which he put down to his half-starved condition. A week ago he began to suffer from great thirst, and noticed that he passed a large amount of urine. Before that he had never been obliged to get out of bed to pass his urine, nor was it excessive in quantity. His appetite was not ravenous. He slept badly, but felt drowsy. His extremities were frequently cold. He has lost flesh rapidly during the last fortnight. He has had no fits, nor loss of consciousness.

Condition on admission.—Patient looks thin, ill, and miserable. His skin is cold, dry, and rough. Tongue bright red, dry, and cracked. His muscles are somewhat wasted. He complains of great thirst and hunger. Breath has a sweet, hay-like odour. There is slight œdema of legs and ankles. Patient passed during the first 18 hours he was in the hospital 92 oz. of urine, sp. gr. 1·033, light-coloured, acid, no albumen, sugar 16 grains per fℨ.

Heart and lungs normal. Mental power good. Temp. 98·6° F.

Patient was put on diabetic diet, and his general condition somewhat improved. He went on passing a large amount of sugar daily.

November 3rd., 5.15 p.m.—Called to patient and found him with cold extremities. T. 94·8° in axilla. P. 120. R. 32, deep and sighing. All respiratory muscles acting strongly. He complains of uncomfortable feeling about rectum. Bowels are confined. Seems dull and drowsy.

Ordered brandy ℨss. statim. Enema olei ricini, statim.

8.30 p.m.—Respiration of same character, but more rapid. He has great pain in region of stomach, ordered ℞. Sp. æther. sulph. ℥x. ammon. carb. gr. vj., aq. ad. ℨj., 4^{tis} horis.

11 p.m.—Has been getting gradually worse. He groans aloud, and now and then cries out. He asks for his brother. When given his brandy he remarked, "it was no good, as he knew he was dying." Brandy increased to ℨvj.

November 4th, 3 a.m.—Lies with eyes closed and pays no attention to surrounding objects, but will answer questions if aroused. He swallows brandy and medicine without any trouble.

5.30 a.m.—Breathing has suddenly changed. There

is now deep inspiration and groaning expiration. He lies with his eyes open, but turned upwards and half covered by the upper lid. Extremities are very cold. Radial pulse cannot be felt. Heart sounds are very indistinct. Patient is completely comatose. Death occurred at 7 a.m.

Abstract of Autopsy.—The left kidney was much atrophied, the calices and pelvis being completely filled with putty-like material. The left ureter was completely blocked with the same material. The right kidney was nearly twice the normal size (9½ oz. in weight), and appeared quite healthy. No lesion was discovered in the brain or spinal cord, both of which appeared quite healthy, hard, and did not tear on section. Lungs and heart healthy.

Remarks (by Dr. Wilks).—This case is one of much interest as favouring the belief in the existence of such a malady as acute diabetes. The strong presumption in support of it can only rest upon the same grounds as those which prove the duration of any illness—the recognition of symptoms denoting a departure from health on the part of the patient or his friends. In this case it was stated, both by the patient himself and by his father, that he had only been ill a fortnight before his death, and there was no reason to doubt the accuracy of their conviction. In medical literature, and scattered throughout the periodicals, cases of a similar kind may be met with, and but lately the attention of the profession was roused to the possible existence of *diabetes acutus* by the fact of a medical practitioner having suffered in his official reputation by the non-recognition of this disease a short time before the patient's death.

In the case above reported, if the patient had not sought advice at his own home until the day previous to his decease, and the medical man, from want of time or carelessness, had not made an examination of the urine, there might have arisen a great difficulty as to the exact cause of death; indeed, it is very probable in many cases where the patients are brought to the hospital in a dying state, and where the necropsy reveals no tangible organic disease, that they may have been the subjects of acute diabetes; in some such cases, however, rheumatism or other form of blood poisoning may be regarded as the latent cause.

The present case may be read as presenting very typically the symptoms which accompany death by diabetes, and which is usually called death by coma. This term is incorrect, if it is intended by it that the symptoms resemble those of death by apoplexy, uræmia or opium. This is not the case; the symptoms are rather those of profound collapse. The patient may very quickly fall into this condition, which is accompanied by an expression of great anxiety, together with restlessness, short breathing, sighing or groaning, whilst at the same time the pulse becomes thready and quick, and the face and hands grow rapidly cold. Very often, too, the patient complains of intense pain at the pit of the stomach. This symptom is very remarkable, but is pretty constant. All this time the patient may be quite rational and clear in his mind, so that there is no coma. Insensibility at last supervenes, as in many other fatal diseases, but it does not seem to have any special significance. I was once called to see a patient dying from diabetes, whom for a moment I thought was suffering from cholera, so great was the collapse and coldness of the body. In another case, severe rigors accompanied all the other symptoms just named, so that a suggestion of a suppurative or more common form of blood poisoning was made. I have seen a great many persons, both in hospital and private practice, die of diabetes, and therefore must pronounce the term coma a misnomer. The distinctive symptoms which mark the end are characterised by pain at the pit of the stomach, prostration, sighing, and apnœa.

Medical Times and Gazette.

SATURDAY, JANUARY 19, 1884.

A serious attack was made at the meeting of the Pathological Society on Tuesday last, on the essential nature of Charcot's joint disease, Mr. Arbuthnot Lane contending, in a carefully-written paper, that the changes found in that affection do not differ in any essential particular from those of rheumatoid arthritis, and denying that there were any distinctive features by which the two diseases could be separated. Many of the speakers who followed showed more or less inclination to accept his views; but we think, with some of the speakers, that due importance should be given to the clinical features of the two affections in endeavouring to decide the question of identity or non-identity. If the joint affection be rheumatic, the lightning pains will have to follow suit and be admitted to be only a coincidence, whereby we should be deprived of what at present is justly regarded as a valuable diagnostic symptom.

At the last meeting of the Ophthalmological Society, the subject of sympathetic ophthalmia cropped up again and occupied a good portion of the evening. Dr. Brailey pleaded in favour of reflex nerve irritation as a direct and indirect cause of the propagation of the mischief to the second eye. His arguments, however, did not seem absolutely convincing, and, until further evidence is forthcoming, we fancy the verdict will be "Not proven." Mr. Eales read an account of a case of paralysis of convergence and accommodation—a case resembling in some features the ophthalmoplegia interna of Hutchinson, and probably due to a central lesion. Mr. Story described the treatment of cystoid cicatrices, and Mr. Silcock exhibited some optic nerves showing an extravasation of blood into the sheath. Living specimens were shown by Mr. Lewis Jones and Mr. A. S. Morton.

In his Bradshawe lecture at the Royal College of Surgeons, Mr. John Marshall supported the theory of the existence of sensory nerve fibres in the sheaths of mixed nerves, although their existence had not been demonstrated. We learn that Mr. Victor Horsley has recently discovered not only sensory nerve fibres but also tactile corpuscles, or end bulbs, lying on the perineurium, and he will demonstrate his specimens at the next meeting of the Royal Medical and Chirurgical Society.

The Fellows of the Royal Medical and Chirurgical Society, and of the other societies which meet in Berners Street, will have learned with deep regret the death of Mr. Wheatley, so many years the Resident Librarian. Mr. Wheatley was born in 1819, and was the eldest son of Mr. Benjamin Wheatley, the auctioneer, of Piccadilly. At the death of his father, in 1837, he

was thrown upon his own resources, and from that time he devoted himself to the care of the family dependent upon him. He early showed that mastery of the art of catalogue-making which distinguished him through life. In 1845 he first commenced to catalogue at the Royal Medical and Chirurgical Society; and in 1855, on the resignation of Mr. Williams, he was appointed Resident Assistant Librarian of that Society. Besides his proficiency as a cataloguer, he was well known as an able analyser and indexer. He made, among many others, indices for the Statistical, Medical and Chirurgical, and Clinical Societies. He was an original member of the Library Association of the United Kingdom, and one of its Vice-Presidents. Mr. Wheatley's accurate knowledge of the resources of the Medical and Chirurgical Library, and his extensive acquaintance with medical literature generally, made him an invaluable helper to those who were at work on any special subject. He was just as ready to assist the youngest Fellow as the oldest official of the Society. His genial and quiet manner but served to enhance the value of his active and untiring industry in the service of the Society. Death took place rather unexpectedly, though he had been complaining for some days previously. The immediate cause was a weak heart, with some enteritis and peritonitis. He was buried on Tuesday last at the Highgate Cemetery, the chief office-bearers of the Royal Medical and Chirurgical Society, and representatives of the Clinical and Pathological Societies, being present.

Under the name "Alliance Française," the *Revue Scientifique* (Dec. 15) announces that a new society has been formed in Paris, having for its object "the propagation of the French language." Several persons, it says, devoted to the spread of the *idée française* in foreign parts, have come to the conclusion that the best way of effecting this is to propagate the cultivation of the French language abroad. "This is a patriotic aim—not that noisy patriotism which sees enemies on every side—but an active and humanitarian patriotism, which, combining the cause of France and that of civilisation, has no thought dearer to it than the increase of French influence. The *Alliance* may encounter some difficulties at first, but we feel assured that some years hence it will become one of the most powerful agents of our development beyond our narrow European boundaries." In pursuit of this somewhat grandiloquent programme, it is proposed to found schools in foreign parts in which the French language will be taught, and to send out to any country in "which the name of France is still beloved" lay missionaries, having in charge the promotion of the cultivation of the language. Among the patrons of the *Alliance* we find the names of General Faidherbe, the Bishop of Algeria, M. de Lesseps, M. Billot of the Foreign Office, M. Léon Say, M. Duruy, Professor Paul Bert, and other distinguished persons.

The most important event of the week for the medical profession has been a meeting held in a school-room in an out-of-the-way suburb. On Tuesday evening the "patients, friends, and neighbours" of Messrs. Bower and Keates, assembled in force at East Dulwich to witness the presentation of a testimonal expressive of their sympathy with, and unabated confidence in, those two persecuted practitioners. The chair was taken by the Rev. T. A. Warburton, vicar of East Dulwich, who stated the case in a most sympathetic speech. "Messrs. Bower and Keates," he said, "came there that night to receive, not their condolences, but their warmest congratulations. Their names would be long remembered in the medical profession as having adopted a course which should act as a warning to the Public Prosecutor in the future to inquire well into the facts of a case before he exercised his functions. The good result of the proceedings had been the establishment, among the medical profession, of a fund for the protection of practitioners, if assailed in the same ungrateful and ungenerous way that Messrs. Bower and Keates had been assailed."

The testimonial, consisting of an illuminated address, two silver salvers, and a joint purse containing one hundred guineas, was then presented. Mr. Bower made an excellent reply. "The subscribers to the testimonial," he said, "had done good to the medical profession, to the legal authorities, and to the public. The Public Prosecutor was, so to speak, green at his work, and the medical profession, so far as they were concerned, had had to teach him his business, though at its own cost. The Public Prosecutor had failed to prosecute in cases which he was asked to prosecute; and he had prosecuted medical men where he ought not to have prosecuted. In the present case, if some of the chief men of the medical profession had been appealed to, the Public Prosecutor would have been told that no prosecution ought to be instituted. He found a poor child suffering from diphtheria, and in such a condition that, if no further steps had been taken, it would have died in half an hour. In order to give it a chance of life, he made an opening in the windpipe. That was an operation which it was the bounden duty of every doctor to perform under the circumstances, and which, if it had been his own child, he should have requested to be performed. True, he was not able thereby to save the child's life, but he prolonged it for upwards of thirty hours; and for aught he knew at the time, the operation might have been successful. He might have contented himself with looking at the little sufferer and saying that nothing could be done; but with the simple desire to save life he performed an operation which was approved in all modern hospitals, and which in 14 or 15 per cent. of cases was successful." Other speeches followed, notably one by Dr. Glover; and the chairman, in dismissing the meeting, stated that the adviser of the Public Prosecutor had written saying that the operation adopted by Mr. Bower was a proper one and could not have been better performed.

Nothing which has happened in the profession for a long time has given greater cause for satisfaction than the way in which the appeal on behalf of Messrs. Bower and Keates has been responded to. Sir William Jenner, and the College which he represents, have

immensely advanced themselves in the esteem of all medical men by the statesmanlike way in which they gauged the importance of the case and the heartiness with which they took it up. The result has astonished and delighted everyone, and will be quoted for years as an answer to those, within the profession or without it, who say that doctors are apt to selfishly wrap themselves up intheir own pursuits. It is difficult, no doubt, to stimulate medical practitioners generally to take any vivid interest in the schemes of medical Bill makers. But when a case is put before them which really touches their generous sympathies, they have shown that they are not slow in responding to the call. If there had been need, many hundred pounds more would have poured in, to indemnify Messrs. Bower and Keates for their unjust usage. The result of the appeal, as Mr. Bower has pointed out, will have a most favourable effect on the profession, every member of which will vividly realize that in doing his work honestly and humanely he will have the sympathy and support of the profession against all cavillers.

The death rate of London, thanks to the mild weather, still continues comparatively low, viz. 19·4. The number of deaths in the week ending last Saturday was 1493, the ten years' average for the corresponding week being 326 more than that, or 1819. Of this fortunate falling off, not much more than half is accounted for by the decline in the number of deaths from zymotic and respiratory diseases, the two classes most influenced by meteorological conditions. The deaths from the former class were 60, and those from the latter class 122 below the corrected ten years' average. Mild weather probably tells on the death rate in ways which are not yet quite fully understood. The most fatal zymotic disease during the week was whooping cough, which caused 63 deaths; while measles caused 47, and scarlet fever 38 deaths. The mortality from diphtheria was 15, and from enteric fever 17, figures which compare very favourably with the latest returns from Paris, where during the week ending January 3rd, there were 56 deaths from diphtheria and croup, and 29 from enteric fever. The deaths from violence were rather more numerous than usual, the number of suicides being 14, or 8 more than the corrected average. There was not a single death during the week from sunstroke.

The Collection made in Dublin on Hospital Sunday, November 11, 1883, amounted to £4,212—a sum considerably in excess of that realised the previous year. Something over four thousand pounds will be available for distribution between the sixteen institutions which participate in the benefits of the Fund.

The twenty-third of the present month is the fiftieth anniversary of the formation of St. Vincent's Hospital, Dublin. A concert will be given on that day, in aid of the funds of the institution, when an ode, specially composed for the occasion by a well-known poet, will be recited.

A meeting will be held on Saturday afternoon, January 19th, under the presidency of the Duke of Westminster, K.G., at the Highbury Athenæum, Highbury New Park, at 4 p.m., to confirm the proposed amalgamation of the Great Northern Hospital and the Central Hospital for North London, and to consider the question of the increased need for hospital accommodation in the northern districts of the metropolis. The Marquis of Salisbury, K.G., the Earl Cowper, K.G., the Lord Mayor, Lord George Hamilton, M.P., Sir Andrew Lusk, M.P., W. M'Cullagh Torrens, Esq., M.P., Octavius E. Coope, Esq., M.P., Messrs. Burdett-Coutts, Townshend Murdoch, Marshall, Lang, and others, have announced their intention to take part in the proceedings. The scheme of amalgamation, which will be submitted to the public on this occasion, will probably be found equally satisfactory to the supporters of the old-established Great Northern Hospital and to those of the projected Central Hospital, mutual concessions having led to a combination at once harmonious and effective. The need for increased hospital accommodation in the North of London has long been recognised by the leading inhabitants of that district, and a keen interest has been taken in the present movement, which will doubtless find clear expression at the forthcoming meeting.

The number of professors at the German Universities is so great, and the reverence of the students so enthusiastic, that the celebration of some form of jubilee or another is a never-ending occurrence. That of Professor Du Bois-Reymoid has only just finished, amidst great enthusiasm, and now preparations are being made to commemmorate the fact that just twenty-five years have elapsed since the renowned clinical teacher, Professor Frerichs, accepted the call from Breslau to Berlin.

During the year 1882–83, the number of medical diplomas conferred in the German empire was 692, against 669 in 1881–82. In the same period 95 veterinary practitioners received diplomas, compared with 121 in 1881–82; and 22 dental diplomas were conferred, against 25 in 1881–82. There were also 315 apothecaries admitted, but the number of these has steadily declined since 1878, when it was 371.

The *Deutsche Med. Wochenschrift* for December 19 announces that the Prussian Government, in anticipation of the renewal of the discussion on the question of limiting the practice of vivisection which is to take place during the present session of the parliament, has issued a circular to the medical faculties of all the Prussian universities, requesting a statement of their opinions on the question. This calls to mind the fact that on the occasion of the interpellation which took place last session, a distinguished physiologist resolved to exhibit to the ministry, in a striking and graphic manner, the relation which vivisection bears to the progress of physiology. Taking the last edition of "Hermann's Manual," he scored all the well-founded facts which could never have been firmly established without the aid of vivisection. When he had done

with the book, it very much resembled in appearance a liberal political journal, which had been submitted, in the worst times, to a Russian censor—the passages struck out, exceeding in number those that were allowed to remain in.

Our Glasgow correspondent writes as follows:—"It appears from the health officer's report that the inmates of the model lodging houses have been re-vaccinated in large numbers, and in order to induce them to submit to the operation each man who accepted vaccination received a week's free lodgings, which is equivalent to a bonus of one shilling and nine pence. In three nights 146 out of 225 inmates submitted to re-vaccination. Of course, many of those who are supposed to have the good of the city at heart take exception to this new way of trying to prevent the spread of so dire a disease as small-pox. The reason for the step appears to have been the fact that an epidemic of small-pox had appeared in the locality in which the lodging house is situated, and it was considered a good plan to get at a number of individuals who wander about during the day and congregate together at night. The demand lately for vaccine lymph has been so great that at the public vaccination stations applicants (medical) were refused, or rather disappointed in securing supplies. It is to be hoped that we shall be spared the horrors of an epidemic; but when we hear of a bonus being given, it may be justly asked, What next?"

The health officer for Glasgow, in his provisional report for 1883, states that during the year there were 14,564 deaths registered, representing a death rate of 28 per 1000 of the population, as estimated by the Registrar-General, and of 27 per 1000 of the population, as estimated by himself. "The death-rate for the years 1881–1882 was 25, and the average death rate for the ten years, 1873 to 1882 was 27. Therefore whatever population we take for a basis of comparision, we certainly have not diminished our death rate in 1883 as compared with the decade immediately preceding, though we are considerably below the average of the ten years 1863–72, which was 31. It is not possible at this early date to go into the details of this increased mortality, but it is apparent that it is largely due to the epidemic prevalence and fatality of the three chief infectious diseases of children—measles, scarlet fever, and whooping-cough."

From the census report for 1881 of the North-West provinces of India and Oude, just published, it appears that out of a total population of nearly thirty-three millions, nearly one hundred and thirty thousand are blind, over six thousand are insane, nearly twenty-eight thousand are deaf and dumb, and nearly eighteen thousand are lepers.

Dr. Dudfield has appended to his last monthly report on the health of Kensington, a summary of the vital statistics of that parish during 1883, in anticipation of the full report to be published later on. The results are highly satisfactory. The deaths, 2,615 in number, were fewer by 76 than in 1882, and 358 below the corrected decennial average. The death rate was only 15·5, having beaten that of 1882, hitherto the lowest on record, by 0·7 per 1,000. It was 2·8 per 1,000 lower than the decennial average of Kensington, and as much as 7·0 below the decennial average of the metropolis generally. This favourable result is in great measure due to the decrease in the number of deaths from zymotic disease, which were only 251, or 199 below the corrected decennial average. The zymotic death rate was 1·5 per 1,000 persons living; the decennial rate for Kensington being 2·6, and that for the whole metropolis 3·5 per 1,000. The mortality from all the zymotic diseases but diphtheria and enteric fever, was much below the average, and considering that these are the two diseases which are perhaps the most likely to yield to sanitary influences steadily applied, we hope that Dr. Dudfield's future summaries will be even more satisfactory to himself and his clients than the present one.

The Government of Bombay has published a long memorandum on the plague among cats, which appeared at Ahmednuggar two years ago, and at Siroor last June. The Government seems to think that the plague may have some connexion with the cholera, and invites opinions on the subject.

We regret to see, from the Leeds papers, that there is some danger of the public losing the rights which they have held from time immemorial to wander at their free will over Ilkley Moor. Those who have stayed at Ben Rhydding, or gone on the tramp through Wharfedale, will remember with affection the breezy expanse of moorland above Ilkley, which is one of the finest of the few open spaces that still remain to the public. It appears that the lord of the manor has set up boards warning trespassers off the moor, on the ground that they interfere with the grouse, to the disposal of which he has a claim. Mr. J. F. Little, of Ben Rhydding, has entered a vigorous protest against this usurpation, and there is no doubt that he will receive such support as will end in securing the recognition of the people's claim to use the moor. In this connection we may quote an extract from a very able lecture on "The Difficulties of Health Reformers," delivered at Edinburgh last Saturday by Mr. Hely Almond. "Road walking," the speaker said, "was a poor sort of exercise; but hill walking, both for the climbing and the strong air, was a very good one. Some of the paths in the hills around Edinburgh were shut up because they did not use them. There was not another country in the world which shut up its mountain land as some people had most audaciously and most unpatriotically attempted to shut up vast tracts of the Highlands, and all for the lounging, sneaking, murderous mockery of sport called deer-driving, and to the injury of healthy sport, and of other things which did the same sort of good as sport—the pursuits of the naturalist, the artist, and the mountain club."

There is one item of news from Egypt of considerable importance. Mr. Clifford Lloyd has obtained permission to introduce sanitary reforms at Alexandria.

The health administration of that city will be entirely remodelled and brought as far as circumstances permit into harmony with English ideas. It is to be hoped that the reforms thus introduced in one corner of Egypt will be steadily and as quickly as possible extended to the whole of the Delta.

We have before us the first issue of the Australasian Medical Directory—a publication which doubtless has before it a most successful future. The want of such a guide to the profession in the southern colonies has long been felt, and the only cause of wonder is that it did not make its appearance years ago. The compiler has been three years in preparing it, and his work has been most ably done. It must be a satisfaction to him to feel that his publication is the first book of reference in which all the Australasian colonies—so soon we hope to be joined in a common league—have been brought together under one heading. The directory follows the lines of the corresponding publication in the mother country. Besides a list of nearly 1,700 legally qualified medical practitioners, resident in the colonies, it contains a general gazetteer of 1,000 post towns, combined with a local directory of all resident physicians, surgeons, veterinary surgeons, and dentists. It also contains an obituary, an abstract of all the principal laws affecting the medical profession throughout Australasia, an inter-colonial official medical directory, a list of scientific societies, the regulations and by-laws of colonial universities, a list of coroners, a recognised scale of medical and surgical fees, a short history of 130 universities in all parts of the world, and a list of medical periodicals published in the English language.

At Paris permission has been given by the Prefect of Police, on the recommendation of Dr. Brouardel, to cremate the remains of hospital subjects, provided a satisfactory apparatus be constructed in one of the Paris cemeteries. A Society for the Propagation of Cremation is in existence in Paris, the president being M. Koechlin-Schwartz, the mayor of one of the arrondissements.

It was not to be expected that the activity and enterprise which are converting the Cambridge University into one of the leading medical schools in the country would escape the adverse criticism of those whose ideal of a university life is one of secluded and self-sufficing contemplation of the past. This latter view is put very cleverly in an article entitled "Unnatural Science" in a recent number of the Cambridge Review. The writer, evidently a follower at greater or less distance of Mr. Oscar Wilde, thinks that natural science clashes grievously with the tone and the surroundings of "this ancient University." He would not however banish it altogether. "The aphorisms of Hippocrates, Aëtius, and Aretæus might well be studied; Pliny and Aristotle have in their range of knowledge and variety of observation been rarely superseded. The Arabian doctors, the Greek botanists, the middle-age physiologers, all help us to understand the past, and that to my thinking, is the chief and highest part of university education." As for the more modern studies, they would be most fitly carried on in our large manufacturing towns, which would be little the worse for the addition of one sight slightly more revolting or a few smells of a rather more atrocious character.

The writer then goes on to inform us that by medicine he does not understand as so many do the barbarities of vivisection, or the finikin pedantries of microscopic research. "Rather I have in my mind's eye the calm-browed disciple of Galen and Hippocrates, pacing the grassy courts of Caius, or the cool alley of the Baeks, his eye ever on the watch for simples and healing herbs—Birthwort, and Herb Benet, and St. John Baptist flower—whose vocation should be to build up instead of pulling to pieces, to heal and rescue rather than to blight and to destroy."

But his main complaint against science is that it dulls the senses of its devotees most fatally as regards the appreciation of beauty, until the mind gets so distorted as to contemplate the structure of an entozoon with greater satisfaction than the east window of King's Chapel. And lastly, he cannot help thinking that the time is near, when we shall only welcome the sight of a sunset for the sake of the aid it may lend to the spectroscope; when we shall only whistle to a dog in order that he may come and be larded with tin tacks, and when the only notice excited by an early Italian fresco will be an exclamation of disgust at the imperfect treatment of the deltoid muscle. If these amusing paradoxes were worth answering, one might point out that many branches of modern science contemplate a past, beside which the past of Hippocrates and the Arabian doctors is but as yesterday. But then it is a past on which man's hand made little impress, and that robs it of interest for our mediæval critic. The difference between the two schools of thought is that the one regards man as the centre of the universe, and nothing of importance except in relation to him, while the other looks on man as a part—the most interesting part perhaps, but still only a part—of nature. A university belies its name which does not embrace both schools.

The Cambridge Special Board for Medicine have just issued a schedule, defining the range of the examination in pharmacy and pharmaceutical chemistry which students proceeding to medical and surgical degrees will be expected to pass. It has evidently been judiciously compiled, and the demands made on the student do not extend beyond what is absolutely essential. The minor drugs, of which so many are still allowed to remain in the Pharmacopœia, are wisely disregarded, and chief stress is laid on the preparation and adulteration of the more important agents, and the proportions of *essential* ingredients contained in their pharmacopœial preparations. The student, moreover, will only be expected to recognise ordinary specimens of the more important crude drugs and of the more characteristic preparations. The authorities have acted very wisely in freeing their students from the useless toil of learning the look of unimportant drugs which no one but here and there an old-fashioned apothecary ever uses.

The juice that Dr. Moxon's pen distils is always stimulating to the mind, if sometimes somewhat acrid, and now and then a trifle turbid. Those who read their *Lancet* carefully will have been struck by some sentences published in a lecture of his last week, which have all the qualities we have defined. It sometimes seems to him, he tells us, "as if the medical mind describes the kind of curve which is called an hyperbola, and that the finite visible and measurable part of this curve is in the region which medicine shares with surgery; whilst the other side of the hyperbolic curve, that which looses itself in the infinite, affords scope for a range of greatness more proper to medicine, allowing play for electro-doctors and room for mastership in dyspepsia, and range for skill in the number of minutes tea should be brewed, and for precise propriety in porridge and potatoes, with other details which, but for infinitude of range, might seem trivial to anyone wanting in faith. But with faith nothing seems trivial. Is not faith the only faculty that can follow hyperbolic curves through the infinite side of their course?" A little later he talks of those "who lend meretricious authority to the vague and indefinite," and then after a sentence, the profound obscurity of which even the most hyperbolic medical mind will fail to penetrate, he tells us that he could say a great deal upon pulmonary *adequacy*, "if he had nothing more definite to communicate." We do not quite catch Dr. Moxon's meaning, unless it be to fling, in passing, a little chaff at certain physicians, who are not quite such skilled pathologists as he. We always think pathologists are to be pardoned when they get out of patience, as they often do, with diseases that make no show in the deadhouse. But still half the suffering in this world, if not more, is caused by functional disease and minor ailments.

It is reported that Dr. Wendell Holmes will shortly come to England on a lecturing tour.

A strange sort of festivity, says *Truth*, took place on Friday, the 4th instant, at the Hospital St. Louis, at Paris. A comic opera, written and composed by the young surgeons attached to the establishment, was performed for the amusement of the patients. Fifty years ago, Charles Fourier, the celebrated philosopher, wrote:—"One day medical science will endeavour to overcome the sufferings of patients by amusing their minds; hospitals will be filled with flowers, and music and plays will be performed there." And yet it was currently reported that Fourier was mad.

There is no profession in which there is so little temptation to downright lying, and so much temptation to fibbing, as that of Medicine. It is so difficult to tell a patient bluntly, "I don't know what is the matter with you," when half a dozen plausible assumptions, any one of which would suffice to save one's reputation and retain the confidence of one's patient, start to the tongue. It is so difficult to say, "Sir, your wife's a drunkard," or, "Madam, you have cancer of your right supra-renal capsule, and will be dead in six months," when a little prevarication would be so much easier and pleasanter for all parties. Here and there, it is true, one meets with a doctor who is tempted in exactly the opposite direction, who loses no opportunity of telling the brutal truth, and who, like Mr. Gilbert's King Gama, is, in everybody's opinion, "a most unpleasant man." While it is difficult to such a man to remember that one has other duties to his patients besides truth, it is difficult for others to remember that they have other duties besides kindness. We are sure that the absolute avoidance of falsehood, expressed or implied, is the best policy for the doctor in the long run, even as regards his own worldly interests; whilst so far as the profession is concerned, there is no single thing which has done it so much harm, in the eyes of the public, as the belief that some doctors hold the concealment of the truth to be justified by the end. On this subject no one's teaching, by precept and example, has been more beneficial than that of Dr. Matthews Duncan, whose remarks in another column will be read, we are sure, with universal approval.

The *Louisville Medical News* for December 15th extracts some interesting passages from the report of the German Consul-General at Shanghai, in relation to the Chinese trade in musk. In China everything smells of musk, both sexes carrying it about in little boxes and keeping it in their clothes-presses. When it is considered that an export of 3,000 catties, each catty containing 15 to 20 pouches of Yunnan, or 20 to 30 of Tonquin musk, means the sacrifice of no less than 60,000 musk deer (and this quantity has been reached several times of late years), and if to this there be added the consumption in China itself, which can scarcely be estimated, it is much to be feared that the entire extirpation of this useful and graceful animal will not be long delayed. Each pouch is wrapped in Chinese paper, and put into a pasteboard box, lined with lead and covered with silk. The boxes are of different sizes, according to the size of the pouch to be packed. They are generally shipped by the mail steamers, being placed in the safe reserved for bullion and treasure. The total export for the last five years was 25,664 catties, or 33,875 lbs., valued at 2,728,800 dollars. The chief port of export is Tientsin—Shanghai and Canton exporting very little.

Some of our readers may be interested to learn that the distinguished physiologist Dr. S. Weir Mitchell, has commenced, in the *Atlantic Monthly* for January, a tale connected with the events of the American Civil War, entitled "In War Time."

We have on former occasions called the attention of our readers to the precarious position of the valuable Index Medicus, instituted for the purpose of supplementing Dr. Billing's Index Catalogue, by furnishing an index of all medical works and original communications in periodical literature which have appeared during the year. This publication, which must prove an invaluable aid to all branches of medical inquiry, is now in imminent danger of coming to a close, from the insufficiency of the support which it has received. The mere cost of its production amounts to 5,000 dollars,

and the maximum return from subscriptions has not exceeded 3,600. The difference has been met by the sacrifices made by its enthusiastic publisher, Mr. Leypoldt, of New York, assisted latterly by a guarantee fund raised by medical bodies and some individual subscribers. It is now felt that this cannot go on, and in a circular just received the publisher announces its approaching stoppage, unless present subscribers will consent to increase their contributions to two guineas per annum, for the mere increase of subscribers at the present rate is quite insignificant. When we consider that the valuable information contained in this work is available in any part of the world where collections of medical works exist, it is humiliating to find that so small a sum should not be forthcoming. At the very least, one would naturally expect that every Medical Society in existence would be found on the roll of subscribers, as well as all learned bodies and academies; and were this so, the appeal now made would be unnecessary. In fact, the negative character of the list of subscribers is most disheartening.

The Library of the Royal College of Surgeons will be closed to day (Jan. 18,) for the purposes of the examinations. We are glad to be able to inform our readers that on and after the 28th inst. it will remain open daily until 6 o'clock, instead of 5 as at present, except on Saturdays, when it will be closed at one.

THE PLETHORA OF CONSULTANTS.

The large number of letters we have received on this subject, a selection from which we again publish this week, forces upon one the conviction that there is widespread and growing discontent with the present state of things. It is quite natural that the consultant who is approaching middle age without seeing any clear prospect of an increase in his income, or of a relaxation in the strain of an enforced economy, should gird at an arrangement which entails on him such hard work and so little pay. It is natural, too, that the successful consultant, with all his weary waiting behind him, and the yellow harvest at his feet, should rebel at the idea of spending his wide experience on coughs and flatulencies, which a journeyman practitioner could conduct to convalescence with equal success. And perhaps it is natural, too, that the journeyman, seeing the master thus occupied with journeyman's work, should resent the higher fees and higher honours which are accorded to him. Against this natural discontent with the present order, one must set off a certain amount of not unnatural content. The eminent consultant who has so gained the confidence of the general practitioners that the larger proportion of his work is such as is worthy of his powers; the younger consultant who has the means and the inclination to devote himself to the scientific pursuit of his profession, more or less regardless of its emoluments; the general practitioner who has so secured the confidence of his patients, that the consultant is to him not so much a dreaded competitor as an ally and support, all these can well afford to be content. But they are few numerically, and their complaisance is drowned by the mass of fermenting discontent, which needs but the slightest touch from the journalist to rush forth in streams of ink. All times of transition are times of discontent, and it does not need a very far-seeing eye to perceive that the present state of things cannot be permanent; but that, after a certain period of confusion, there will be a new arrangement of atoms, and probably a separation at a different and more definite line of cleavage than at present obtains.

Many causes have combined to produce that plethora in the ranks of the consultants, which seems to be at the bottom of "the present discontents." The enormous increase of late years in the number of hospital appointments open only to consultants, the growth of wealth which gives a staying-power to so many young practitioners, the spread of scientific interest, and the more or less fictitious and conventional social line which separates the consultants from the general practitioners, all these influences have drawn men into the higher branch of the profession who would otherwise have entered the lower. As consultants there is not enough work for more than a third of them; the natural result is that the majority either have no private practice at all, or are compelled to undertake work which should properly fall to the family doctor. They become, in short, as far as their private work is concerned, general practitioners in all but the name. The general practitioners, on the other hand, in many parts of London, are pressing upwards; they have washed their hands of dispensing, shaken off the little surgery that used to fall to them, raised their fees, and, in some cases, taken the membership of the College of Physicians. These processes will go on; the consultants attached to the smaller hospitals who cannot hope to gain much true consulting practice will slowly sink, the general practitioner in the better neighbourhoods will slowly rise, until a recognition of the changed order becomes necessary. The word "consultant," it is to be hoped, will be restored to its proper meaning, the term "general practitioner"—always a hideous one—will be dropped, and the title of physician will be claimed and used by everyone who is in any way connected with the College in Pall Mall. The smaller hospitals, if they then still exist, will be manned from this new class, and the consulting branch will be recruited from the staffs of the large hospitals and from those connected with the smaller hospitals, who by their gifts, their industry, and their experience have entitled themselves to the respect and confidence of their brother practitioners.

When hospital appointments are thrown open to the men who now stand in the rank of general practitioners, the sole obstacle which now prevents an able and earnest worker in the lower grade from rising to the higher will be removed. It seems a commonplace—though it is one that is often forgotten—to say that the main *raison d'être* of the consultant is to consult. We are all, however, too apt, when a young consultant's merits are being canvassed, to ask, "What has he written? What researches has he made? Is he a Fellow of the Royal Society?" Now no one can value more highly than we do the fruitful labours and the scientific zeal of many of the younger consultants, and well-searched as the field of medicine has been, it is impossible for a man with a seeing eye to pass

over it without finding something which may well be called an original discovery. But it should not be forgotten that all this is something given in, something additional to the main work demanded of him. The business of the consultant is so to train himself by hard work in ward and dead-house as to entitle him to the confidence of the profession and the public. He may have experimented with every drug, and stained sections of every cubic centimeter in the body, but if at the same time he has neglected the systematic and careful observation of disease, he has failed in his mission. Many men have gained the confidence of the general practitioners—who, by the way, are not the most lenient critics—and been celebrated as consultants, who have never added a new fact to medicine—witness the late Sir Thomas Watson; and there are many on the other hand who have won a name in the scientific world for their original researches, to whose opinion on a clinical case the intelligent general practitioner would not attach the slightest importance. Research, especially if well advertised, may be successful in attracting a certain sort of *clientèle;* but the soundest consulting practices have always been founded on hard work and good teaching in the hospital ward. This sort of practice is not to be made in a day, indeed, the man who aspires to it, if he is honest with himself, can hardly feel fit for it until his hair begins to grow grey. If the best of our young consultants could feel sure that they would eventually attain this goal, they would probably be content with their present position. It is the prospect of failing to obtain it after so many years of fruitless labour, through the number of their competitors, that takes all the heart out of their life and work.

AUSCULTATION OF THE ŒSOPHAGUS.

Attempts have frequently been made to establish some trustworthy means of diagnosing affections of the œsophagus and stomach by the aid of auscultation. The act of swallowing of necessity gives rise to certain sounds, and it is to the correct interpretation of these that we must look before making use of any modification of them in determining morbid conditions. A recent discussion upon the subject in the *Berliner Medicinische Gesellschaft* introduced many points of interest, both from physiological and clinical points of view. The *idea* that deglutition is chiefly effected by means of the action of the constrictor muscles and of the peristaltic movement of the œsophagus has lately been opposed by a theory propounded by Kronecker and Meltzer, who divide the act into two parts, of which the first consists in the rapid injection of the masticated food or fluid through the œsophagus, and the second in the further injection of the food through the cardiac orifice by the contraction of the lower segment of the œsophagus itself. The act is a very rapid one. The every-day experience of the sensation of swallowing may certainly be held to corroborate this theory. Hot or irritant fluids invariably make themselves felt at the upper and lower parts of the œsophagus only, a result probably due to the fact that it is at these points that they are forcibly squeezed against the mucous membrane. If the theory is correct, it is there also that they remain for a few seconds at rest. The pathological appearances produced by corrosive irritants are likewise most marked at the same points. The sounds produced by these two spasmodic movements, by which the food is thus "squirted," so to speak, down the œsophageal tube, may be distinctly heard on listening at the side of the ensiform cartilage. A first sound, coincident with the upper œsophageal contraction, is described as resembling that produced by discharging a syringeful of air under water; the second, following it after an interval of about seven seconds, is said to be somewhat similar, but coarser in character, and corresponds with the opening of the cardiac orifice and the spasmodic injection of the food through it into the stomach. Unfortunately for the diagnostic value of these auscultatory signs, their occurrence is not absolutely constant in healthy persons, although present in a very large majority of the cases examined. Neither is there perfect agreement between individual observers as to the character and relative intensity of the sounds produced. Almost identical noises are heard over the stomach when the œsophagus is at rest, and they may even be set up by electrical stimuli. The subject is one which deserves attention, and especially in relation to affections of the œsophagus, which have, from the earliest days of medicine down to the case of the late Comte de Chambord, presented insurmountable difficulties to the most able diagnosticians; but until a standard can be determined to form a physiological starting point, the efforts to interpret the auscultatory phenomena in the œsophagus will remain as futile as heretofore.

CLINICAL PAPERS.

No. IV.—Aural Vertigo.

It must be evident to many practising our profession, and especially to those who see many aural patients, how frequently the subjects of Menière's disease and aural vertigo are overlooked. Not only are the slighter cases of aural vertigo mistaken for dyspepsia with headache, but even the severer forms, with very obvious symptoms, are ignored. Again and again are patients seen who have been assured that the stomach only is out of order, when the first complaint should have directed attention to the ear. To be able at once to attribute the distressing symptoms from which such patients suffer to the right organ of the body is a position which all members of the profession should be able to assume. With a little care, even the milder cases, in which only occasional and slight giddiness is complained of, may be easily detected. Giddiness of a certain kind should arouse suspicion. Aural vertigo is always very sudden, and occurs at irregular intervals. In severe cases, however, the patient may be continuously giddy, with exacerbations in severity. A man may have one or more attacks of giddiness, particularly at the onset of disease of the labyrinth, and then remain perfectly free for a very variable time. The next attack, after a longer or shorter

interval, occurs quite suddenly and without any warning. It is astonishing how often these paroxysms are noticed in the early morning in bed, the patient being awakened suddenly to find his bed revolving in one or other direction. The probable explanation is, that he has inadvertently turned over from one side to the other in his sleep. Such patients are invariably unable to look under a table without stooping in the vertical position. They cannot turn quickly, or look up at the ceiling. They dare not walk in the dark or with closed eyes. Any movement which would suddenly alter the position of the fluid in the labyrinth brings on an attack.

These, and many other similar facts, one gradually hears in the course of practice; and hearing such a description, the rest may be generally extracted from each and every patient who is the subject of these diseases. For confirmation of the suspicions thus aroused, one would expect to find that the patient was the victim of a constant noise in one or both ears, increased generally when the attack of giddiness comes on to a loud whistling sound. Finally, on examination with the watch applied to the bones of the skull, one or both ears would be found deficient in hearing power. Consequently, the association of these three signs—giddiness, noises in the ear, and distinct loss of hearing by direct conduction to the auditory nerve—would at once put the case under the term that is described generally rather vaguely as "Menière's disease." This name is more properly confined to a smaller branch of such cases to which the term "apoplectiform" is added, on account of the suddenness and severity of the attack, caused either by an extravasation of blood or an inflammatory exudation in the labyrinth. These three signs should not fail to draw the attention of the practitioner to the patient's ear. One would imagine that such deafness could not escape observation; but sometimes it is very slight at first, and the imperfection is only discovered on comparing it with the condition of another person's ear—most frequently that of the practitioner. Or the disease is only present in one ear, and the other being good the deficiency is not noticed. Having decided that the ear is at fault, it becomes necessary to examine the auditory canal. Unfortunately the ear is frequently syringed without such an examination, the consequence being that in the absence of wax the patient is only made more giddy than he was before. Having proved the presence of wax by inspection, "the greatest triumph of aural surgery"—namely, the use of the syringe—may be put in execution. There are, however, few cases in which the presence of wax is the sole cause of aural vertigo; and we would strongly insist upon the necessity of a thorough and careful examination for all those general causes, such as anæmia, which may be attended with aural symptoms, particularly in an already partially disabled ear, and which quickly yield to general treatment.

Presuming, then, that these general causes have been carefully considered, and the auditory canal cleared of its contents if there be any, the condition of the membrana tympani and middle ear must be examined. If such an obvious lesion as a perforation with recent inflammatory exudation is found, these must receive careful and patient treatment before any definite prognosis is given, for the labyrinth itself may be, and probably is, affected in a similar manner by its proximity to the tympanum, and on the subsidence of the inflammation all unpleasant symptoms may disappear. By far the larger class of cases, however, of labyrinthine vertigo are found to be without any definite cause such as this, and one finds the signs of chronic interstitial disease of the middle ear, or an absolutely normal membrane. In the former case, it is believed that the pressure of the stapes upon the fluid of the labyrinth causes the vertigo and noise which accompanies it, and that treatment by inflation through the Eustachian tube cures or relieves this condition. That it relieves the noise for a time there is no doubt, but it is open to question whether the giddiness is in any way improved. In the case of a normal membrane (which is found in a large number of the patients we are here considering, and in most of those with chronic dry catarrh or interstitial disease of the middle ear), little or nothing can be expected from treatment. We have, however, the satisfaction of knowing the course the disease will probably run, and the condition in which it will probably leave the patient.

The length of time over which the disease is spread is very variable, as patients undoubtedly get much better for a time and again relapse. But each return brings with it increasing deafness, till finally, if both ears have been affected, the deafness is almost complete. If one ear only has shown the deficiency of hearing to the watch on contact, or to the tuning-fork, and there are loud whistling noises, then the result of absolute deafness in *one* ear may be expected. This, however, leaves a man a comparatively useful member of society. But in either case the giddiness in the end disappears; and, considering the torture that patients suffer from this alone, it is a crumb of comfort by no means to be despised. Years sometimes elapse before this takes place; but intervals of comparative freedom from annoyance at times occur, and each relapse is generally less severe than the last, leaving the patient, however, more deaf than he was before. Without attempting to differentiate between the various forms of aural vertigo—on which too much stress, to our mind, is laid by the aurists of the day—yet a little more attention to this possible cause of giddiness is much needed by the general body of the profession. When, therefore, giddiness is complained of, and the suspicion is aroused that the ear is at fault, we may expect to find it accompanied by distinct and distressing tinnitus, and when impacted wax is not the cause, additional confirmation is obtained by the application of a watch or tuning-fork as before described. K.

The late Mr. John Flint South.—A life of this gentleman, so well known from his long connection with the Royal College of Surgeons, of which Institution he was twice elected President, and for so many years Surgeon to St. Thomas's Hospital, will be published in a few weeks by Mr. John Murray. The author, Prof. Feltoe, of St. David's College, Lampeter, has had excellent facilities for doing justice to the memory of an honoured member of our profession.

REVIEWS AND NOTICES OF BOOKS.

Diseases of the Bladder, Prostate Gland, and Urethra; by F. J. Gant, F.R.C.S. Fifth Edition. Baillière, Tindall, and Cox, London—This publication has proved that it supplies an acknowledged want, by having reached its fifth edition. Its range is wide, and includes a number of subjects concerning which the student or junior practitioner frequently desires to refresh his memory, and which hitherto it has not been usual to discuss at length within one volume. Mr. Gant says he covers more ground than is covered by any other English author in a single work, and we see no reason to dispute his statement, although the American writers Van Buren and Keyes have even gone further, and in their excellent work on Diseases of the Genito-Urinary Organs, have included syphilis, and the functional diseases of the genital organs. Mr. Gant's treatise consists of his own experience, together with such information as the student can only gather from the combined works of Sir Henry Thompson, Mr. Berkeley Hill, and last, but by no means least, from Dr. William Roberts' classical manual on Urinary and Renal Diseases. The author has been so anxious to make his book useful to the practitioner, that he has devoted space to subjects which do not ordinarily come under the title he has chosen, such as the description and treatment of ruptured perineum in the female, of orchitis in the male, and of congenital malformations of the anus and rectum. At the same time he omits syphilis, and the functional disorders of the genital organs, which, with a little pressure, might have been brought in under the heading of Diseases of the Urethra. Moreover, the first forty pages are given up to the anatomy of the urinary organs, which we cannot help thinking somewhat unnecessary in a practical clinical handbook.

We have nothing but praise for the intention of the author, he gives full credit to all fellow-workers when it is deserved, and evidently endeavours to omit nothing which he thinks will be useful to the class for whom he writes. It is therefore in no unfriendly spirit that we would suggest a few corrections and additions for a future edition. In the first place, beginning with the anatomical section, it is hardly correct to describe the bladder as a hollow organ, and the urethra as a membranous tube, having a diameter of a quarter of an inch at its widest part. Such a description is liable to lead to error in practice, and accordingly we find on turning to the treatment of gonorrhœa, that the patient is directed, when using a urethral injection, to press the urethra in front of the scrotum, to prevent the injection leaving the penile urethra. As a matter of fact, this use of the finger is unnecessary, the urethral walls, during life, being always in contact, held together by their muscular fibres, and no fluid can penetrate further than it is forced. The bladder is never hollow, it is often momentarily empty of urine, but even then there is no hollowness. The realisation of the fact that the bladder never contains an empty space is most important when the living bladder has to be washed out, and lotions applied to its interior.

Mr. Gant has little to say about the removal of tumours from the bladder, he makes very slight mention of the progress that of late has been made in this department of surgery, only noting that Sir Henry Thompson and Mr. Berkeley Hill have each removed a tumour successfully from the bladder. No mention is made of the remarkable series of twelve cases of operation which the former surgeon brought before the Royal Medico-Chirurgical Society last June, or of the other surgeons who, during the last six years, have operated successfully in these cases. It is important to impress upon readers of a handbook that patients afflicted with tumour of the bladder must die miserably if left alone, and that a certain number of these cases may be saved if submitted to bold surgical interference.

The chapter on stone in the bladder is full of interesting and instructive matter, and is evidently written with a full knowledge of the subject. As however nothing can be more distressing after a well performed lithotomy than to lose the patient from primary or secondary hæmorrhage, we are not satisfied to find secondary hæmorrhage dismissed in a few words, "compression will here prove more effectual than ligature." Such instruction is not very clear to the beginner, and it would have been well to have drawn his attention to the best means of plugging the wound with lint soaked in perchloride of iron, or explained to him the use of the light, cleanly, and efficacious air-tampon of recent introduction.

Turning to lithotrity, we find the modern operation with complete and immediate evacuation of the fragments, curiously grafted on the older text, written we suppose before Prof. Bigelow had published his principle, the truth of which is now universally admitted, and which has revolutionised the operation of crushing stone. In consequence these pages are not as clear and definite as they might be. In passing we may draw attention to an error in the drawing of the lithotrite in fig. 30. A large stone is grasped between the blades, but the handle is represented with the male blade screwed home, which under the circumstances is an impossibility.

In addition to lithotomy and lithotrity, the solution of stone in the bladder by medicines taken by the mouth, and also by electrolysis, is given much prominence. Dr. William Roberts is largely quoted from, and his experiments are so referred to as to lead the student to expect greater results from the administration of alkalies by the mouth than he will meet with in actual practice. Still, taking the book in its entirety, it is one which the young surgeon may read with interest and profit, especially if he has previously acquired from larger and more systematic works a sound general knowledge of the subject.

Practical Clinical Lessons on Syphilis and the Genito-Urinary Diseases; by F. N. Otis, M.D. New York: Bermingham and Co., 1883, pp. 576.—Within the last few years a large number of excellent systematic treatises on syphilis have been produced in America. The tone of our transatlantic brethren on the question of the ultimate curability of syphilis is remarkably hopeful, and some authorities, indeed, estimate the cures at upwards of 95 per cent. of all cases. This would lead us to infer that either they have to deal with a milder and less virulent form of the disease than is prevalent in the old world, or that their treatment is on the whole superior to our own. Broadly stated, the American plan of treatment consists in the exhibition of small repeated doses of various mercurials, which are continued for a considerable length of time, that is, for a period of from one to three years, and the iodides are mainly reserved for the treatment of the gummous deposits of the tertiary stage, if indeed these occur at all. The observations of Professor Keyes have exercised a wide influence in this matter. He found, by examination of the blood, that small doses of mercury in syphilis, continued for either a short or long period, not only increased the number of the red corpuscles, but maintained them also at a high standard. This tonic plan of treatment as he has termed it, is now very generally advocated in America, and with the best results. In the present work these points are lucidly put forward, and illustrated by the details of many well-told and instructive cases. Among others, a series of eight cases of syphilis of the finger in medical men is well worthy of attention. Dr. Otis's volume differs, however, from many of its predecessors, by going less minutely into the anatomical and histological detail of the various syphilitic manifestations in skin, bones, and viscera, its scope as implied in its title being essentially clinical and practical. It is made up of a number of short chapters, which were originally given as "class-room lessons" to students; the first half of the volume deals with syphilis, and the second with gonorrhœa and its treatment. As a consequence of its somewhat fragmentary compilation, we find throughout the work a certain want of continuity and coherence in the descriptions, as well as a considerable amount of needless repetition. Apart, however, from such comparatively slight blemishes, much valuable and suggestive material may be found scattered throughout its pages. On the subject of tertiary syphilis, Dr. Otis advances some novel considerations. He proposes the

substitution of the term "period of lymphatic obstruction," for the older names of "tertiary" and "quarternary syphilis." In the active stage of syphilis, as he points out, there is much rapid cell proliferation, which finally induces more or less mechanical interference in the lymphatic system, and accordingly, as was shown by Hutchinson, the more severe and prolonged the secondary or active period of syphilis is, the more severe are the subsequent tertiary gummatous lesions. On this view the gummy infiltrations of so-called tertiary syphilis are merely sequelæ of the earlier stage of the disease, and therefore a gentle and prolonged mercurial course at this time may either entirely prevent, or will at all events greatly mitigate, the later manifestations, by producing fatty degeneration and absorption of the cellular elements, which are blocking the lymphatic system. Dr. Otis brings forward many arguments in favour of his view, and in the latter section on gonorrhœa fully describes his method of dilating-urethrotomy. For these, and many other points, we can recommend a perusal of this volume.

ABSTRACTS AND EXTRACTS.

SURGEON-GENERAL HUNTER ON THE CHOLERA IN EGYPT.

We gave in our last issue a fairly full abstract of Dr. Hunter's paper on this subject. It will therefore suffice to supplement it with a brief *resumé* of the more important evidence on which Dr. Hunter formed his opinion, that cholera has been epidemic in Egypt since 1865, taken by the courtesy of the editor of the *British Medical Journal* from Dr. Hunter's paper, published in full in that periodical.

1. Cases of cholera were said to have occurred in a Greek school at Damietta antecedent to the outbreak on June 22nd. (1) Two Coptic priests informed Dr. Hunter that a Coptic boy, aged five years, belonging to their school, had died with all the symptoms of cholera on June 17th. (2) A Greek priest said that last May one of the scholars at the Greek school, aged eight years, was attacked at Damietta with excessive vomiting and prostration, but had no purging; no details as to suppression of urine. The lad was taken to Mansourah, where he died in twenty-four hours.

2. Positive evidence obtained from Dr. Dutrieux.—Two Greek children died at Damietta April 27th; one day's illness, cyanosis, aphony, algid state, no vomiting, no diarrhœa. Another Greek child, ill about six months; vomit, cramps, aphony, algid state, without diarrhœa; death after six days. Arab barber, ill two or three days, towards end of April, after vomit and diarrhœa. Arab shopkeeper, dead after twenty-four hours' vomit and diarrhœa.

3. Dr. Ambron stated, that in 1867 he saw a case in the person of Dr. Giovanni Martini, who, being called out at night, wrapped himself up in a woollen scarf which he had used only during the epidemic of 1865. A few hours later he was seized with fainting, then with vomiting and diarrhœa, and had all the phenomena of cholera, with the algid state and aphony, but recovered.

4. Dr. Sonsino met with the following in Cairo:—"T. B., of Leghorn, lapidary, seized with cholerine on May 13th, 1873; suffered from diarrhœa, vomit, algid state, and sunkenness of the eye cavities; recovered after twenty hours. In November, 1874, the same man was again attacked with cholerine, but recovered."

5. Dr. Rabitsch stated, Sept. 19th, 1883, that in the year 1878 or 1879 he was called to the Hotel du Mercure, and found there a man whom he pronounced to be suffering from cholera; the patient recovered.

6. Dr. Fouquet had under his observation in September, 1881, a very grave case of cholera nostras, which closely resembled Asiatic cholera; the patient recovered.

7. Dr. Sierra, a medical officer of the European Hospital at Alexandria, stated on July 31st, 1883, that he remembered well, after the small epidemic of 1866, seeing cases of cholerine in Alexandria. By cholerine he meant a copious vomiting and diarrhœa, accompanied by a marked fall in the pulse, agitation, sinking of the eyes. He mentioned such a case to a colleague, and was told that similar cases had occurred in the town; but never more than two or three in a year. Dr. Sierra referred to cases admitted, in the spring of 1883, to the European Hospital at Alexandria, which Dr. Mackie described as two typical cases of cholera.

8. Dr. Mackie has supplied notes of four cases which fell under his own observation. Two in the summer of 1881; another in the summer of 1872, which ended fatally; a fourth in the summer of 1872 or 1873, in one of the sisters of the Deaconesses' Hospital.

9. Dr. Kartulis furnishes a suspicious case as having occurred in September, 1881.

10. Dr. Mamlouk mentions, August 27th, 1883, two cases—one, of a suspicious character, occurred about eight years previously; another, a typical case of cholera, about four years previously.

11. Dr. De Castro, six or seven years ago, saw a case which recovered. About three years previously a case came under his observation and recovered. This patient had had a former attack in 1865. The second attack resembled the first, and presented all the phenomena of cholera.

12. Dr. Demech states that, since 1865, not a summer passed without his seeing one or two cases, more or less severe, of cholera nostras, but in 1866 he had two fatal cases in Europeans in Mansourah.

13. Dr. Fouquet had under his observation, in Sept., 1881, a very grave case of cholera nostras, which closely resembled Asiatic cholera. The patient recovered.

14. Dr. Haddad, of Assiout, states that Dr. Mazurakis, in Dec., 1882, had a patient who died with symptoms of vomiting, purging, cramps, and collapse, after ten or twelve hours. At Assiout, Dr. Haddad states that a man who arrived from Cairo on July 28th, when the epidemic was at its height, and who died of cholera the following day, was entered in the Government registers under the head of "choleriforme." The inhabitants of Assiout "laughed" at this being considered the first case of cholera which had occurred there.

15. Dr. Patterson, H.M. Consular Surgeon, Constantinople, states that he practised in Egypt from 1855 to 1868, both in Cairo and Alexandria, and cannot recall a year during that time without several well-marked cases of cholera having come under his notice, and which were conveniently classed under the head of "cholera nostras." No one, he says, acquainted with the disease could doubt that cholera—by whatever name it might be designated—was endemic in Egypt.

16. Surgeon-Major McNally shows that, in the neighbourhood of Zagazig, diarrhœa with vomiting had existed since last January, and had proved fatal to two hundred persons; that great mortality had taken place from cholera at Chibin-el-Kom prior to the report of its occurrence at Damietta; that, in certain villages in the neighbourhood of Benha, cholera had appeared before the reported outbreak at Damietta, and in one village the deaths were said to have numbered more than fifteen a day.

17. Mr. Honman states that numerous cases of cholera had occurred in Mahallet before the existence of the disease was officially recognised on July 16th; that at Miniett-el-Samanoud and other villages there had been an epidemic in the month of May, as many as four a day dying out of a population of 4,000.

18. Mr. McCullough, an inspector in the Department of the Minister of the Interior, while engaged at Menzaleh, near Damietta, in investigating a judicial case, states that he was convinced by overwhelming evidence that cholera had been raging in the Island of Matariah, on Lake Menzaleh, a month before it broke out at Damietta.

Rheumatic Subcutaneous Nodules.—M. Troisier sums up our knowledge of these bodies in the following description. They are small subcutaneous tumours projecting more or less markedly. Sometimes they are not visible to the naked eye, and can be only made out by palpation, or by putting the skin over them on the stretch. When they occur in the vicinity of joints, flexion or extension of the joint, as the case may be, usually renders them more prominent. They vary much in size, they may be no bigger than a pin's head, or they may be as large as an almond.

They are usually spherical or ovoid, but sometimes disc shaped; their margins are generally well defined. Of firm consistence, they are elastic rather than hard, but pressure does not alter them. The skin is freely moveable over them, and they are often, to a certain extent, moveable on the tissues beneath them, and are adherent either to tendons, superficial aponeuroses, the ligament in the neighbourhood of joints, or to the periosteum. The skin over them is neither red hot, nor thickened. They may be painless. They appear suddenly, and develop rapidly, but occasionally their evolution may be gradual. They usually come out in successive crops, and may last from a few days to some weeks; their absorption takes a longer time than their development; they never leave any permanent traces behind them. They may be found about any of the joints, at all the superficial bony prominences, *e.g.*, the patella, malleoli, olecranon, scapula, crest of the ilium, bones of the hand and the surface of the skull, especially the forehead and occipital region, over the spinous processes of the vertebræ in the ear, and in fact anywhere that they can develop in the superficial aponeurosis. They are often symmetrically arranged. As regards their anatomical seat and minute structure, he is of opinion that they originate in the fibrous tissue of tendon, ligament, aponeuroses, and periosteum, and push their way into the subcutaneous tissue, from which however they never arise, and to which they never become adherent. They are composed of an embryonic tissue, showing at some points more or less of organisation and undergoing in places a necrobiotic change or process of molecular re-absorption. In other words there is a new growth of connective tissue taking origin from the fibrous tissue, but never arriving at such a complete stage of evolution as to deserve the title of fibrous tissue. This view offers a ready explanation of their temporary character, and their tendency to disappear completely. They belong essentially to rheumatism, both by their co-existence with other rheumatic manifestations, and by their mode of evolution, which, in some respects, recalls the shifting and fugitive character of the latter. They are not in themselves of any gravity, and call for no special local treatment.—*Progrès Médical.*

The Doctrine of Acetonæmia in reference to Diabetic Coma.—In the *Progrès Médical* (Nos. 50–51, 1883), MM. Cornillon and Mallat argue, on the strength of one closely observed case, against the theory that the comatose state in diabetes is due to the presence of acetone in the blood. With their opening assertion, that coma is a rare termination of diabetes, we fancy that physicians in this country will not be disposed to agree, for it is generally regarded as the most common termination of diabetes in young subjects. Less objection certainly can be taken to their conclusion, that acetonæmia cannot be considered as the direct and absolute cause of diabetic coma; this accords well with the opinions expressed when the subject was under discussion at the Pathological Society not long since. The authors further conclude, also, that the reddish-brown tint imparted to the urine by perchloride of iron, and the rose tint by sulphuric acid, may be obtained in cases of long standing diabetes quite apart from any coma. These reactions bear no direct ratio to the amount of sugar present in the urine, and they are not usually found in fat diabetic patients; distillation or an intense and prolonged exposure to heat prevent these reactions, cold has not the same effect. In healthy persons, as well as the subjects of diabetes, perchloride of iron produces in contact with the saliva a reddish-brown colour.

Kairin in Enteric Fever.—Dr. T. A. McBride, of the New York Hospital, speaks well of this drug, administered in seven-grain doses every hour until the temperature fell to about 101°F. In addition to lowering the temperature it usually induced copious diaphoresis after a few doses. No bad results had followed its administration in small doses. (*N. Y. Med. Jour. Nov.* 17, 1883).

Cactus Grandiflorus in Cardiac Affections.—This drug is commended in cases of failing heart in which digitalis appears inoperative, or even harmful: also in nervous cardiac affections—palpitations and neuralgic feelings of soreness about the heart. Possessed of apparently the same qualities is the *Cereus Bonplandii*—also introduced by Parke, Davis and Co.; and remedies, exhibiting allied physiological action, are Casca—the ordeal poison of Africa (Lauder Brunton); *Strophanus hispidus* (Professor Frazer); and the dajaslk, or arrow-poison of Borneo (M. Brandoun). Dr. M. O'Hara, in a paper contributed to the Philadelphia County Medical Society on the use of *Cactus Grandiflorus* (night-blooming Cereus) concludes:—1. That Cactus is a pure cardiac tonic, whether for functional or organic disturbances, especially in cases of mitral regurgitant disease. 2. Convallaria, though not of service in cases of mitral regurgitation, appears to be a supplement to digitalis, not replacing it; specially serviceable in backward pulmonary distension from mitral obstruction; and is a fine tonic for nervous or functional cardiac disturbances. 3. Belladonna and strychnine may frequently take the place of digitalis with advantage. 4. Caffeine citrate is ineffectual in heart affections, whether functional or organic. (*New York Med. Jour. Nov.* 17, 1883).

The Vomiting of Pregnancy. — American "*popped corn*," salted to taste, is recommended by Dr. T. C. Wallace as having been found, during four years' experience, to be "always a beneficial, and generally a sufficient remedy." How much of its value is to be attributed to the psychical action of a method of treatment both novel and not unpleasant? (*Med. and Surg. Reporter, Feb.* 17, 1883).

The Blistering Treatment of Acute Rheumatism. —Dr. Francis P. Kinnicut has published his experience of this method, which in England is connected with the name of Dr. Herbert Davies. Struck by the success which seemed to have attended Dr. Harkin's modification of it —so far, at least, as regards speedy relief to pain, control of pyrexia, and shortening of the illness—he determined on putting his form of the treatment into practice in certain acute cases of rheumatism, and in one of acute gout, in the wards of St. Luke's Hospital. A blister was applied over the entire cardiac area, and repeated as soon as the condition of the skin permitted; no internal medication was employed beyond small doses of opium given at night and when demanded by acute pain. The histories of five consecutive cases are given in full detail. He concludes that this treatment affords the best results yet attained in controlling the arthritic symptoms and the pyrexia; but that it seems incapable of hindering or of preventing subsequent inflammations of the endo- and pericardium, and of other serous and fibrous structures. He lauds the administration of the salicyl compounds, so given that the economy may be kept continuously under their influence, continued in the initial dose throughout the first ten days of the disease, and then given in very gradually diminished amount during the patient's entire convalescence. And he speaks highly of oil of wintergreen, in doses of two and a half to three drachms daily; it is best given in sealed capsules. (*New York Medical Record, Dec.* 8, 1883).

REPORTS OF SOCIETIES.

THE OPHTHALMOLOGICAL SOCIETY OF THE UNITED KINGDOM.

Thursday, January 10th, 1884.

Jonathan Hutchinson, F.R.S., President, in the Chair.

Congenital Absence of Lacrimation on one Side.

Mr. A. S. Morton exhibited a child in whom no tears flowed on the left side during crying. It was presumed that the lacrimal gland was absent, or ill developed on this side.

Hæmorrhage into the Sheath of the Optic Nerves.

Mr. A. Q. Silcock showed preparations of the optic nerves as illustrating this occurrence. The patient was a man who died in St. Mary's Hospital, eight days after re-

ceiving a fracture of the skull. He was delirious during life, and no examination was made with the ophthalmoscope. After death, a fissured fracture was found traversing the posterior inferior angle of the right parietal bone, and the right half of the occipital bone, extending from a point two inches above and four inches behind the right external auditory meatus, to the jugular foramen of the same side, the middle and anterior fossæ were intact. There was much extravasated blood in the cavity of the arachnoid, especially over the base of the brain. The sheath of the left optic nerve was much distended, and discoloured near the eyeball from extravasation of blood into it; the clot occupied the subdural space. Mr. Silcock observed that, in Graefe and Saemisch's *Handbook*, it was laid down that such extravasation only occurred in fracture of the base, or through the optic foramen, but in the present case there was no fracture in these regions.

Symmetrical Disease in the Yellow Spot Region.

Mr. WARREN TAY exhibited an infant, aged about six months, showing a peculiar degeneration of the retina and choroid about the macula, quite symmetrical in each eye, and also double optic atrophy. He reminded the members, that during the first session he had exhibited an infant suffering from a precisely similar affection, and the case had been recorded, and a drawing given in the first volume of the Society's Transactions. That child had died, but no post-mortem examination had been permitted. It was the eldest child of the same parents. The second child had also precisely similar changes in its eyes. The present was the third child. It had been brought to him first when six weeks old with double optic neuritis, and at that time there were no changes at the macula. The mother had had no other children, and these were all boys. Mr. Tay did not offer any hypothesis in regard to these cases, but he thought the changes could not be due to embolism.

The PRESIDENT considered that the fact that the disease was perfectly symmetrical in all the cases absolutely negatived the possibility of their being due to embolism. It was important to note that all the children were males, and that there was no consanguinity in the parents. It was essentially a family disease. The retina and optic nerve seemed to be too frail to bear the wear and tear of everyday life. The disease bore some analogy to Kaposi's disease of the skin, in which the skin could not bear exposure to the sun; this affection, too, usually occurred in one sex in a family.

A Case of Sympathetic Conjunctivitis.

Dr. BRAILEY showed a patient, æt. 66, whose right eye had been injured about sixteen months earlier. It was excised on November 29. The left eye began to discharge soon after the accident to the right, and there was still a considerable gummy discharge. It was no better after excision of the right eye, but rather worse.

Mr. J. B. STORY (Dublin) thought that it was rather stretching the use of the term, to attribute the conjunctivitis in this case to sympathetic inflammation. He did not see in its occurrence anything more than a coincidence. It was very desirable that our list of sympathetic affections should not be lengthened.

Mr. ADAMS FROST asked if there was any peculiarity in the course of the disease, or any obstinacy to treatment, that had caused Dr. Brailey to attribute the conjunctivitis to sympathy. Was the fact that the eye had not improved after the removal of the damaged one regarded as evidence of sympathetic disease?

Mr. NETTLESHIP asked what treatment had been adopted for the injured eye; as, if atropine had been used and the eye covered up, an acute conjunctivitis might have been developed out of a chronic one.

Dr. BRAILEY, in reply, stated that he did not know what the original treatment of the damaged eye had been. His reasons for regarding the conjunctivitis as sympathetic were—1, That the eye had been previously perfectly sound; 2, That it resisted all treatment; and 3, That it became worse after the removal of the other eye. Then it must be admitted that the patient had hypermetropia, but vision was very good with glasses. He (Dr. Brailey) believed that conjunctivitis was often due to sympathetic inflammation.

Pseudo-Glioma.

Mr. H. L. JONES exhibited a child, æt. 2 years, the subject of this affection. On October 4 the child had a fall, and two days later was convulsed, with fever, squint, vomiting, and retraction of the head. Four days later there was acute iritis in the right eye, and optic neuritis of the left eye. At the end of three weeks the fever left the patient, but a yellowish white reflex was seen inside the right eye, and the tension of the eye was found to be much diminished.

Congenital Double Pupil.

Dr. BEEVOR exhibited a boy, æt. 9, who presented a peculiar condition of the pupil of the left eye. The pupillary aperture was double, each aperture acting to light and during accommodation vision in this eye was defective. With the right the patient could read Sn 1½, with the left Sn 3. In reply to Mr. Frost, he said that there was no history of syphilis.

The PRESIDENT suggested that possibly the condition was due to a persistent pupillary membrane.

Sympathetic Ophthalmia.

The discussion on this subject, adjourned at the last meeting, was resumed.

Mr. SPENCER WATSON said that one form of keratitis had been described as very common—viz., keratitis punctata. This condition he was familiar with in syphilis, rheumatism, and in cases quite apart from any cachexia, but he had not seen it in sympathetic ophthalmia. What was meant by sympathetic ophthalmia? A second eye might become affected with the same disease as the first, owing to the same cause. After removal of an inflamed eye, as a rule the second eye improved. What was to be regarded as distinct evidence of sympathetic ophthalmia?

Dr. BRAILEY said that sympathetic inflammation was often of a particular character, viz., dots on the posterior surface of the cornea. In syphilis such dots were very rare; they were still more rare in rheumatism. He believed that they were always present in sympathetic ophthalmia, and in this opinion he was confirmed by the experience of Mr. Milles. Sooner or later, dots would be sure to be present. He believed in the existence of sympathetic conjunctivitis, and sympathetic neuritis. The causes of sympathetic mischief were manifold—plastic inflammation, serous inflammation, punctured or non-punctured wounds. He did not think there was any evidence whatever of direct transmission from one eye to the other, and he thought that we must fall back upon the theory of reflex nerve irritation; this was not supported at present by any direct clinical or pathological evidence, though it was by indirect. A foreign body in one eye might produce injection in the second; this did not differ in any material respect from a conjunctivitis with discharge, and therefore might be regarded as an inflammation. Sometimes inflammation attacked the second eye after removal of the first; here there could be no direct transmission, nor could it be directly due to reflex nerve irritation. But by his hypothesis this latter condition had produced an impaired nutrition of the sound eye, which was thus more liable to be attacked by disease.

Mr. J. B. STORY (Dublin) could not allow this theory to pass unchallenged. No one had yet produced inflammation by reflex irritation of a nerve. Sympathetic ophthalmia possessed certain peculiarities: thus irido-choroiditis, if produced by sympathetic inflammation, was peculiar in its course. If caused by simple reflex action, removal of the other eye ought to have a much greater effect than it had If caused by direct transmission, then the removal of the cause would not have much influence. All diseases had at one time or another been attributed to sympathetic influence. Congestion from nerve irritation did not run on to inflammation, nor did the congestion of one eye from a foreign body in the other lead to sympathetic opthalmia. His own experience did not permit him to say whether keratitis punctata was constant or not.

Mr. ADAMS FROST thought that the distinction between congestion and inflammation was clear and definite: in the one the secretion was normal in character, in the other

mucopurulent. The fact that sympathetic ophthalmia might set in after enucleation of the injured eye was against the theory of direct inflammation, but not against that of the spreading by continuity of tissue. That sympathetic irritation differed from sympathetic ophthalmia was proved by the difference in the effect of removal of the injured eye.

Mr. Nettleship agreed that Dr. Brailey ought to have given his cases in greater detail, and hoped he would add them as an appendix to his paper; at present he had not proved his position, and the doctrine that irritation might lead to inflammation was a dangerous one to hold unverified. The occurrence of diffuse keratitis, due to sympathetic inflammation, had not been sufficiently dwelt upon. The optic nerve was frequently inflamed in the early stages of sympathetic ophthalmia, but this differed from the ordinary neuritis or papillitis, in that it was not uncomplicated, but occurred coincidentally with disease of all the other structures of the eye. This was a very important point to remember. As to the mode of transmission, it was very difficult to prove its non-transmission along one or other of the ciliary nerves; and before rejecting this theory, we should recall the complete change our opinions had undergone during the past few years, as to the mode of transmission of optic neuritis.

Mr. Waren Tay had observed punctate changes on the surface of the lens in sympathetic ophthalmia, and asked Dr. Brailey as to the length of interval that had elapsed in his cases after the removal of the injured eye before the onset of the sympathetic inflammation.

Mr. Lawford said that if there was a spreading of the disease by continuity of tissue, it was remarkable that it should never spread in other directions (*e.g.*, to the meninges) as well as to the other eye.

Mr. McHardy alluded to a case he had already published in the St. George's Hospital Reports, where conjunctivitis occurred three weeks after the removal of a damaged eye, and spread in spite of treatment, ultimately developing into a typical sympathetic ophthalmia. He also spoke of the occurrence of keratitis punctata with serous iritis as a disease almost exclusively confined to females. There was an absence of constitutional taint, but generally some nervous disturbance, *e.g.*, climacteric period, or some uterine derangement. It commenced in one eye, but almost invariably, after an interval, the second eye was attacked.

The President confirmed from personal experience the observation of the last speaker. There was in women a very remarkable and very obstinate keratitis punctata, occurring in both eyes, and quite apart from gout, rheumatism, or syphilis. Possibly we should some day admit the existence of neurotic ophthalmia, *i.e.*, a nervous change not spreading from one eye to the other. Perhaps some forms of rheumatic inflammation were of this nature. Keratitis punctata was not a good indication of sympathetic disease.

Dr. Brailey, in reply to Mr. Tay, could only say that the period was considerable; as to what constituted sympathetic ophthalmia he said, that if in ordinary eyes the liability to conjunctivitis were as 1 to 1000, and if, where one eye was lost, that liability was 1 to 100, then he would say that such great liability was due to sympathetic action.

A Case of Paralysis of Convergence and Accommodation.

Mr. Eales read notes of the case of a little girl, aged 13 years, who came under his care on June 1st last, suffering from complete suppression of all power to converge the eyes, together with paralysis of accommodation and the associated contraction of the iris in each eye, though the pupils reacted well to light. From the history of the case, it appeared that this condition began in March last. The patient had never menstruated, had always had good health, having suffered from no illnesses except the usual complaints of childhood, and a mild attack of typhoid fever, uncomplicated by relapses or sequelæ, and none of them related in point of time with the occurrence of the ocular affection. Her mother died of tubercular phthisis. Her father was a subject of gout. There was no evidence or suspicion of syphilis, or of diphtheria, no history of headache or vomiting. The patient was spare and slight, but apparently a healthy and cheerful child. On examination, the bilateral movements of the eyes in all directions, except convergence, appeared to be normal. The disc and fundus of each eye was healthy. Acuity of vision was good in each eye ($=\frac{15}{12}$). The field of vision was normal, and colour-vision good. There was no other evidence of organic nervous disease. Patellar tendon-reflex was normal. There was no evidence of anæmia. Treatment by strychnia and potassii iodidi had no effect on the ocular condition which persisted to the present time. In the absence of any evidence of coarse intracranial disease, Mr. Eales attributed this condition to a degenerative change in those nuclei of the third nerve which had been shown by Hensen and Völckers to preside over the functions lost, and to be situated in the neighbourhood of the aqueduct of Sylvius; but what had caused this degeneration, he did not venture to predict, in the absence of any clear indications.

The Treatment of Cystoid Cicatrix.

Mr. J. B. Story (Dublin) advocated the use of nitrate of silver in the treatment of cystoid cicatrices. In one of 5 mm diameter, occurring after a cataract extraction, he cauterized about a dozen times in the course of a month, having previously split open the cyst with a Graefe's knife. The cure was perfect, and so far permanent. Mr. Story corroborated von Graefe in assigning a very small opening between the cyst and the anterior chamber, and even suggested that in some cases no such communication existed at all. In the case treated by him, no effect was produced on the anterior chamber by the escape of the fluid. He also, like von Graefe, had found the tension generally subnormal in these eyeballs, and had found hernia iridis a frequent forerunner of cystoid cicatrix, but the hernia was not to be regarded as either the cause of, or the first stage in, the growth of the cyst. The eye tolerated the nitrate of silver perfectly, vaseline being applied to prevent the effects from spreading too far. Mr. Story suggested that the actual cautery might be used with equally good results in these cases.

CLINICAL SOCIETY OF LONDON.

Friday, January 11th.

Sir Andrew Clark, Bart, President, in the Chair.

Subcutaneous Nodules occurring in an Adult not the subject of Rheumatism.

Dr. J. Kingston Fowler read notes of a case of this affection.—The patient was a man, æt. 35, a railway porter, who came as an out-patient to the Middlesex Hospital, on Oct. 26, 1883, complaining of loss of appetite, pain in the epigastrium after taking food, and emaciation. There was no history in the family of syphilis, gout, or rheumatism. He had been fifteen years in the 2nd Life Guards without being in hospital a day. When 25, he had gonorrhœa, and a sore on the glans penis, the latter was probably not specific. Three years ago he first noticed a lump beneath the right patella, it was then small and slightly tender. This gradually increased in size, the tenderness soon disappearing. About one month later a similar swelling appeared beneath the left patella, and gradually increased in size. Nodules appeared beneath the elbows shortly after. These remained, but no fresh ones appeared until four months ago, when he discovered a small one near the right trochanter major; it

was tender—and is so still—to a slight degree. This disappeared in a few weeks, but re-appeared after an interval of one month, and has since grown steadily. Shortly after its second appearance, a similar nodule was noticed near the left trochanter major. Similar growths have since appeared over the buttocks. On close examination as to any history of rheumatism, the only fact bearing upon it elicited was that for the last two years he has had occasional pain about the knees after working hard, and then resting; the pain would occur perhaps two or three times a week. For the last six weeks he has complained of almost complete loss of appetite, with pain after food, and constipation. He has lost a stone and a half in weight. The nodules are arranged with almost perfect symmetry, and present the following general characters: — They are subcutaneous, nearly all are separable from the skin and from the subjacent structures, and are freely movable. The skin overlying and around them is normal. They occur singly, and also in large clusters, some of the large masses consisting of congeries of smaller ones. The single nodules are hard and shot-like to the touch, the larger masses are lobulated, and not so firm. They are not painful; but one near the right trochanter major is slightly tender. The distribution of these growths is as follows:—*Right arm*—On the posterior surface of the ulna three nodules situated about two inches from the olecranon, one as large as an olive, the others the size of peas. *Left arm*—Two nodules in like position, and of about the same size. *Ischial tuberosities*—Beneath the skin, which in the sitting position overlies the ischial tuberosities, there are on the right side six nodules forming a single mass, the size of a Tangerine orange—a rather smaller nodule is present on the corresponding spot on the opposite side. *Great trochanters*—Two inches below and a little behind the right trochanter major there are two collections of nodules forming a ridge about equal in size to a walnut; on the left side there are two smaller masses. Below each patella there is a nodule the size of a walnut. A small nodule is present below the internal condyle of the right femur, and another over the anterior surface of the right tibia. Reference was made to the original communication of Drs. Barlow and Warner, describing the occurrence of subcutaneous nodules, similar in many respects to those found in this case, in children and adolescents the subjects of rheumatism, and also to the cases of two adults, related by Dr. Stephen Mackenzie and Dr. Dyce Duckworth, in the last volume of the Society's Transactions. It was pointed out that in the situation, symmetrical arrangement, free mobility, absence of pain or infiltration of overlying integument, these growths were similar to those found in association with rheumatism, and also that the situation of the growths had probably been determined by the irritant effects of pressure. Further experience may prove that they occur under a variety of conditions which have hitherto been overlooked.

Dr. Duckworth said the case closely resembled one brought forward by him last session. He had also seen cases of nodules occuring in children chiefly about the patella; in adults he had found them often over the ulna. He thought Dr. Fowler's case showed that there were several varieties of these nodules. In adults, the nodules differed from those found in children, in being larger and harder. They also differed in this respect, that in children they often disappeared in a few months, while in adults they did not pass away. The only effectual treatment in adults was to excise them. In some cases the rheumatic history was vague and heart disease was not present.

Dr. Barlow, in answer to the President, did not think that all these nodules were necessarily rheumatic. He had found similar looking nodules in a gouty subject; but on examination they were proved to contain urate of soda. Since the paper by Dr. Warner and himself was published, he had had an opportunity of observing some further cases. In regard to treatment he referred to one in which no cardiac affection was present, and in which he had tried salicylate of soda in gradually increasing doses. The nodules however, increased, and a cardiac murmur appeared in due time. Subsequently the nodules passed away. In some cases he had found repeated blistering successful in causing the disappearance of nodules of small size. He had not found iodide of potassium of any use.

Dr. Mahomed mentioned a case illustrating the disappearance of such nodules. The patient, a female, had subacute rheumatism, but no heart complication. Two subcutaneous nodules which she had disappeared in a few days under the use of salicylate of soda. He would like to hear from Dr. Barlow in what proportion of cases of rheumatism such nodules were present.

Dr. Glover referred to a case of subacute rheumatism, in which some nodules were present, which disappeared partially under the use of iodide of potassium and carbonate of ammonia.

Mr. R. W. Parker thought that these nodules appeared more frequently in cases of subacute than of acute rheumatism. As to their exact position, he had removed nodules on five different occasions, and had always found them situated on the outer surface of the fibrous aponeurosis. He asked where the gouty nodules referred to by Dr. Barlow were found.

Dr. Lee also referred to a case, and spoke of the connection of these nodules with rheumatism and chorea. In his case, the nodules were limited to the right side of the body, where the chorea also showed itself most marked.

Mr. Lucas could corroborate the remarks of Dr. Duckworth as to the difference between these nodules in adults and children. He referred to a case in which salicylate of soda and iodide of potassium had been used without good effect, and he had subsequently removed the tumours in the hospital. The patient, a female, had no rheumatic history, and no heart disease.

Dr. Gilbart Smith had seen two cases in adults without rheumatic history or heart disease.

Dr. Money held that in children, at least, these nodules occurred very frequently He thought that they would be found in probably half the cases of rheumatism. He had seen them disappear in the course of four days. He agreed with Dr. Barlow as to their value in the matter of prognosis.

Dr. Fowler, in reply, drew attention to the fact that in his case all the nodules occurred in spots subject to pressure.

Cortical Tumour, with Great Variety and Frequency of Epileptiform Seizures.

Dr. Coxwell contributed a case of the above affection:—Ten years ago, G. R., a young man, then æt. 20, began to suffer from fits, which always had as their starting point the right hand, and never had a greater range than the right arm and right side of the face. Five years later he came under the care of Dr. Gowers at the National Hospital for the Paralysed and Epileptic. He was admitted as an in-patient for the last time in February, 1882, under Dr. Radcliffe, who kindly permitted the publication of the case. He then had optic neuritis in the left eye, but not in the right. There was some paralysis of the right arm and right leg, but none of the face. The deep reflexes were all in excess on the right side, with right foot clonus. Dr. Coxwell during eleven months was enabled to make careful observation of the mode of onset of many of his epileptiform seizures. When the fits were frequent, an hour spent at his bedside was rewarded by a view of several fits. As the time was summer, he could lie without danger with his limbs uncovered, and if they were placed in a position of semi-flexion or semi-abduction, as the case might require, the slightest initial movement could not fail to attract attention. In the numerous cases of cortical tumour which have been recorded, the fits have nearly

invariably been described as beginning in the same place. In this case, however, during the last year of the patient's life there was great variety in the starting place and range of the fits. The patient died in January, 1883. A large number of Dr. Hughlings Jackson's statements with regard to epileptiform seizures were exemplified in this case. Mention, for instance, was made of temporary paralysis of right side of face, or of right arm, caused by fits affecting these parts; of the connection between the occurrence of aphasia and fits affecting the right side of the face; of the fact that when spasm spreads from the side first affected to the other, it passes to the leg of the second side and not to the arm or face. The patient had every variety of fit, including some of the ordinary epileptic type, characterised by sudden loss of consciousness and general convulsion. It had been stated that these fits do not occur in such cases; perhaps the greater and widely spread instability which this kind of fit implies was the result of the extraordinary frequency of the fits, and the great duration of the case (ten years). There was a tendency at different times for some special type of fit to occur, sometimes the face alone being affected, sometimes chiefly the right arm, sometimes the whole of the right side, and so on. Perhaps the explanation was that the tumour created instability in cortical areas adjacent to that in which there were pathological changes, and that when the instability reached a certain degree of intensity, explosive discharges occurred in them, causing spasm in corresponding sets of muscles. The spasm having attacked the arm, nearly invariably proceeded upwards—extremely seldom downwards. One never saw a twitch at one joint—say the elbow—then a twitch at the knee, and then at the mouth. In each case, on the contrary, there was a definite line of march of the spasm, either up or down a limb. These facts seemed well explained by the localisation theory. The tumour was found at the autopsy to be a glioma affecting the posterior parts of the first and second frontal convolutions, and the extreme summits of the ascending frontal and parietal convolutions on the left side. Its position therefore corresponded very fairly with what one would have expected, from the fact that during the first nine years of his illness the spasm always commenced in the right hand. This man often had 200 or 300 fits a day. In the last year of his life, 21,800 fits were counted.

Dr. Beevor had had an opportunity of seeing the case, and could corroborate the account of the fits given by Dr. Coxwell. He had tried, by tapping the head, to localise the seat of the lesion, and found tenderness corresponding to the part where the tumour was found. He had made observations as to ankle clonus in ordinary cases of epilepsy, and found it increased for about five minutes after the fits.

Dr. Glover would like to hear if the patient had ever hurt himself in any of his fits.

Dr. Coxwell, in reply, stated that he also had noted the tenderness spoken of by Dr. Beevor. As regards personal injury, he had not found that the patient had ever sustained any in the fits.

Annual General Meeting.

The business of the Annual General Meeting was then entered upon.

Election of Officers.—The President read the report of the scrutineers of the ballot, Dr. Gilbart Smith and Dr. Hadden stating that the list proposed by the Council had been unanimously approved.

Mr. Warrington Haward (the Secretary) read the report of the Council for the past year, from which it appeared that 21 new members had been added to the roll of the Society, and eight members had been removed by death. Three committees had been appointed during the year.

The Treasurer, Mr. Heath, submitted the financial report, which showed a balance in the banker's hands of £160 11*s.* 2*d.* He made also a feeling reference to the great loss which the Society had sustained in the death of Mr. Wheatley, whose continuous and ready aid those engaged in the business of the Society had so much cause to appreciate.

Mr. Gant proposed that the report of the President and Council, together with the Treasurer's report, be received, adopted, and printed in the Society's Transactions. This was seconded by Dr. Glover, and carried unanimously.

Dr. Cholmeley moved, and Dr. Duckworth seconded, a vote of thanks to the retiring vice-presidents, Dr. Broadbent and Mr. Lawson, and to the other retiring members of the Council, for the services they had rendered during their several terms of office. This was carried unanimously.

Mr. Berkeley Hill proposed a vote of thanks to the retiring secretary, Mr. Warrington Haward, paying a high compliment to the manner in which he had performed the duties of the office. Dr. Frederick Taylor seconded the proposal, and the vote was unanimously accorded.

Mr. Haward, in reply, said he esteemed very highly the vote just passed, taking it to mean that the Society considered that he had at least done his best. He had been fortunate in being associated with such colleagues in the secretarial office as Dr. Taylor and Dr. Coupland. He had been well repaid for any labour which the office entailed, by the interest and instruction which he had always found in the meetings of the Society. With regard to the loss sustained by the Society in the death of Mr. Wheatley, he wished to express the feeling of sorrow with which those, especially who had been secretaries, must miss the kind and courteous help which Mr. Wheatley was always so willing to give. Mr. Wheatley had rendered to the Society most valuable aid.

The President could endorse all that Mr. Haward had said regarding Mr. Wheatley, whose amiability and well stored mind must have impressed all who came into contact with him. He would sum up all his many excellent qualities by saying that Mr. Wheatley was an upright man.

Mr. A. Pearce Gould then gave a demonstration of the use of the endoscope with the aid of the electric light. The appearances of the healthy urethra were first demonstrated: and subsequently those characteristic of gonorrhœa were well displayed.

PATHOLOGICAL SOCIETY OF LONDON.

Tuesday, January 15th, 1884.

J. W. Hulke, F.R.S., President, in the Chair.

At the commencement of the meeting the President made a graceful allusion to the great loss the Society had sustained in the death of Mr. Wheatley, and stated that the Council had passed a resolution expressive of their sympathy with his family.

Two Cases of Mediastinal Tumour.

Dr. Norman Moore described these:—1. Endothelioma of the pericardium. Microscopic sections were shown, with drawings, of a new growth found in the pericardium, and of secondary new growths from the lung, clavicle, and supra renal capsule. The growth consisted of abundant large, flattened, nucleated cells of an endothelial type, contained in well-marked alveoli. In all the places on which it was found, the new growth was of an absolutely uniform structure. The specimens were from a man, aged 37 years, who was under his care in St. Bartholomew's Hospital. His illness began with shortness of breath and hæmoptysis, and lasted about five months. On admission he complained of severe pain about the sternum. The breathing sounds were natural and the heart sounds clear. The cardiac impulse was feeble. His breathing became more and more rapid and laboured, and he had paroxysms of urgent dyspnœa. On September 24 a swelling was noticed on his left clavicle; it was firm, but not very hard. On October 3 his chest gave

the following physical signs: Absolute dulness behind, from the spine of the scapula downwards. Over no part of the dull region were vocal vibrations quite absent, and at the extreme base some sound, as of air entering the lung, was audible. A subcrepitant rale was to be heard just below the root of the left lung. Exactly over the root of the left lung faint bronchial breathing was to be heard, but no bronchial breathing anywhere else. In front there was a peculiar hyper-resonant note just below the left clavicle, and elsewhere on the left side absolute dulness. The right side was normal, and so were the heart sounds. Three days later dulness had increased upwards on the left side, and in the evening he decided on paracentesis, and 27 oz. of clear serum were drawn off with an aspirator. After this, a loud rough sound was heard over the lower part of the left back. His dyspnœa, which had been very urgent, was relieved, but became urgent again in two days, and on October 10 he died. His evening temperature had been raised throughout. It was usually above 100, and often above 101. On the following day a post-mortem examination was made. The pericardium was much distended, and contained bloodstained fluid. At the base of the heart, and for one-third downwards upon its surface in front, and two-thirds downwards behind the visceral layer of the pericardium was infiltrated with a whitish firm new growth, and this extended to a somewhat less extent on the parietal surface. The muscular substance of the heart was nowhere penetrated. At the root of the left lung the new growth had penetrated the main bronchus for half an inch, and actually formed its wall. It extended a little way only into the lung. Both in front and behind, the mass of new growth was in contact with chest wall, thus explaining why, in spite of a large pericardial effusion, the heart sounds were distinctly audible, and why, in spite of the pleural effusion, neither vocal vibrations nor air sounds were quite absent over the region of dulness. The lump on the clavicle was associated with some wasting of the bone, and was firmly attached to the bone as well as the periosteum. The bronchial glands were involved. Below the diaphragm the new growth was only to be found in the supra renals, both of which were infiltrated and enlarged. There was no pigmentation of skin. The clinical features, as well as the naked eye appearances, pointed to the conclusion that the new growth began in the pericardium. Its microscopic structure pointed to its having originated in the endothelium of the pericardium.

2. Microscopic section, with drawing of a new growth which occurred in the mediastinum of a man aged 18, who died in St. Bartholomew's Hospital, under the care of Dr. Gee. The growth was a round-celled sarcoma, with a meshwork and spaces resembling those of a lymphatic gland, and was of a type often found in the mediastinum. The patient was ill about two months. The mediastinal tumour was made out during life. There was a pleurisy of the right side, from which 50 oz. of sero-purulent fluid were drawn off. The evening temperature was for a fortnight above 100°, and for the last month, during which the pleuritic physical signs became more distinct, was above 101°. Post-mortem: A new growth was found upon the upper and outer part of the pericardium. It pressed upon the trachea and the aorta, and occupied precisely the position of the thymus gland in a child. The new growth extended above the clavicle, involving the lower cervical lymphatics. The right lung was adherent to it, and the adhesion only infiltrated. No other organs were infiltrated. In the last four years Dr. Moore had examined, post-mortem, six other cases of new growth in the mediastinum. In all recent pleurisy were present, as it was in the two shown that evening. This observation, and the fact that two tumours of such different histological appearance were both associated with rise of temperature, pointed to the conclusion that the rise of temperature in cases of mediastinal new growth was due to the attendant pleurisy, and not to the nature of the new growth.

Mr. BUTLIN said the great question was whether these were cases of endothelioma or not. No doubt it was much more common than usually believed. It was difficult to determine the origin of these growths. Two distinct kinds were recognised—one with cell nests, the other like hard or soft cancers, both very malignant. Dr. Moore's case belonged to the second group.

Mr. JESSETT spoke of a case of mediastinal tumour he had seen, in which there was no pleurisy.

Mr. CROFT referred to the character of the fever; it might be hectic or continuously febrile.

Dr. GOODHART said that many cases of tumour with rapid cell growth had no fever. He referred to the case of a lady, who died of cancer of the gall-bladder with a little peritonitis.

Mr. MORRANT BAKER said that variable fever was not diagnostic against tumour, as had been generally supposed.

Dr. MOORE referred to Dr. Church's paper in St. Bartholomew's Hospital Reports, pointing to hectic fever as evidence of lymphosarcoma; a belief he considered erroneous, as he attributed the fever to pleurisy.

Dr. DUCKWORTH spoke of the attacks of fever that were observed in these cases, coming and going without other symptoms; he was inclined to attribute them to the growth of the tumour.

Mollities Ossium.

Mr. ARBUTHNOT LANE showed the bones from a case of mollities ossium of the bones of the skull, the occipital, temporal, and sphenoid were alone affected, more externally on left than on right side, and the inner table more than the outer. The progressive line of softening was very apparent. It did not extend across the sutures to the adjacent bones. The softened bone showed a decalcified zone with what appeared to be the depositions of decalcified lamellæ of new bone on it. The sutures were loose, allowing of free movement, the ribs, pelvis, and scapula presented apparently ununited fracture with fibrous union. These, however, proved to be due to a very rapid decalcification of the bone at the point of greatest strain, accompanied by periosteal and endosteal deposit, causing the thickening. The articular cartilages of left knee-joint were extensively ulcerated; there was a good deal of bony growth on the margin of the condyle and patella. The right knee, elbow and shoulder-joint presented the same appearance. The temporo-maxillary articulations were destroyed, especially on the right side. He also showed the bones from a case of rheumatic arthritis, which presented symmetrical affection of the temporo-maxillary elbow and hip joint. The heads of the femora were enlarged, and presented in the centre of the convex articular surface, a loose disc of bone and articular cartilage. He considered that Charcot's disease was merely rheumatic arthritis affecting a patient with feeble osseous system. The bones of cases of Charcot's disease were very light and porous. The wasted bones of a feeble patient, as in an old ataxic underwent a rapid retrocession to the fibrous condition under the influence of rheumatic arthritis.

Mr. CROFT asked why this was a case of rheumatoid arthritis. Some reform was needed in the classification of joint diseases. Many cases were called rheumatoid arthritis without any clinical evidence.

Mr. HULKE thought the term was often used rather loosely, and perhaps without much evidence of rheumatoid arthritis.

Mr. Eve said that rheumatoid arthritis and Charcot's disease were very similar, but yet there were great differences. In Charcot's disease the articular surfaces of the bones were much worn away, far more than in rheumatoid arthritis. In the latter the surface was always eburnated. In Charcot's disease the nervous system played an important part in preventing repair by damaging the nutrition.

Dr. Duckworth believed that rheumatoid arthritis and Charcot's disease were quite distinct; careful observation proved this. He said that pathology must be corrected by clinical observation. Mr. Lane had not alluded to the extreme effusion into the joint in Charcot's disease. Mr. Eve's suggestion was very probable.

Dr. Norman Moore said we ought to have a good reason for calling these cases of mollities ossium.

Dr. Goodhart thought that for the present Charcot's disease must be open to criticism, partly because the cases were very rare. Had enough cases been met with to justify a separate class being made for it? Did morbus coxæ senilis differ from Charcot's disease?

Mr. Eve believed that Charcot's disease was rheumatic arthritis with nervous changes.

Dr. Hale-White had lately seen three cases of Charcot's disease, with enlargement of the ends of the bones. A pamphlet had lately appeared, showing that no sharp line could be drawn between cases where there was much "bossing" about the joints and cases in which there was no outgrowth.

Dr. Ormerod thought that we could not decide this question on anatomical grounds alone. Charcot's joint affection began in a peculiar way—*vide* the effusion without pain or fever. He referred to a paper by Pitres and Vaillard on the subject of peripheral neuritis.

Dr. Money had seen great muscular atrophy in cases of joint disease, and thought therefore that peripheral neuritis was no argument.

Mr. Bowlby said that the absence of pain was not a proof of the absence of inflammation, and instanced the case of a whitlow.

Mr. Hulke did not know the anatomical difference between rheumatoid arthritis and Charcot's disease. He referred to a case of Mr. de Morgan's at the Middlesex Hospital, with bony outgrowths. A second case had similar changes, with signs of disease of the nervous system.

Mr. Lane briefly replied: he thought that if he had been able to show the specimens of temporo-maxillary articulations, they would have been universally admitted to be cases of Charcot's disease.

Section of Galls.

Mr. Cripps said that a large class of insects of the hymenoptera tribe were the cause of the galls, and not the ichneumon fly; the latter bores his way in and deposits ova in the body of the cynips. Different galls affected different parts of the same tree, caused by different animals; he then briefly described their structure, and mode of growth, and repair.

Dr. Cobbold referred to a monograph by Mr. Fitch on the subject.

Mr. Shattock, as regarded the reproduction of the epithelial lining of the gall, said, that scar tissue never produced hair. The gall might be formed by involution of the leaf. It would not be very likely to be produced from the epithelium, as suggested by Mr. Cripps. There was no proper retiform tissue.

Mr. Eve said, that by admitting that a parasite might cause a tumour, we were taking a great step. We should all admit that an irritant could cause a tumour.

Mr. Cripps briefly replied.

Secondary Localised Emphysema from Minute Emboli.

Dr. Heneage Gibbes (in connection with the investigation being made jointly with Mr. J. B. Sutton, into Tuberculosis in Birds) had examined a number of animals with morbid changes in their lungs and other organs. In their former paper, read by Mr. Sutton last November, they had shown that most of a certain class of birds had become tuberculous, and animals fed on these birds had also become tuberculous. This portion of the inquiry they were still pursuing, and they had obtained some very important facts which they hoped to bring before the Society in a short time. The two cases brought forward by Dr. Gibbes were—(1) That of a Koodoo antelope, the fresh lungs of which appeared to be studded with tubercles. These, however, disappeared on hardening the organ. On making sections, they were found to consist of small emphysematous areas, caused by minute emboli which had blocked up the vessels and cut off the blood supply from these areas. This had probably taken place some time previously, death having occurred from pneumonia. (2) Nematode worms in the lung of a Beatrix antelope. There were nodules under the pleura, not visible to the naked eye, but which could be felt on passing a knife over the surface. On section, these were found to contain the parent nematode worm, and ova in every stage of development up to the larval form. The parent worm was not coiled up, but twisted through the lung substance. Dr. Gibbes had not been able to dissect out the whole length of the parent worm from want of time. A section of the parent worm showed a number of ova in the abdominal cavity which corresponded exactly with those found in the lungs. The ova showed the various stages of development, until the larval form was reached. No intermediate forms between this and the parent worm were found. Dr. Gibbes considered that at this stage, it sought some other host, as he found numbers in the bronchial secretion. In January, 1882, the Koodoo antelope was found to be suffering from a copious discharge from the nose and mouth. In a few days all the animals in the antelope's house were similarly affected. The Koodoo died, but the Beatrix recovered. About two months later she was again taken ill, and gradually wasted and died. Dr. Gibbes had not been able to find any similar case recorded. Drawings and microscopical specimens were exhibited.

Dr. Cobbold said that many animals perished annually from parasitic lung diseases. He had seen in various animals forms in their larval condition quite indistinguishable from that shown to-night. Only two forms had hitherto been seen in antelopes and deer up to the present. He believed that this was an example of *strongylus rufescens*, which had not as yet been seen in antelopes.

GENERAL CORRESPONDENCE.

THE PLETHORA OF CONSULTANTS.

[To the Editor of the Medical Times.]

Sir,—Your correspondent "M.D." seems to me to be combating a phantom. Did anyone, unless perhaps some perfervid junior, ever maintain the proposition he is puzzled to understand, that "the 'consultant,' the hospital physician or surgeon, is *necessarily* a superior person to the 'general practitioner,'" or make the assumption which he denies, that "a man is a leader because he is a consultant?" If such notions anywhere really exist, they may be safely left to refute themselves.

"Consultants" of some kind, men specially selected to give an opinion in doubtful or difficult cases, I suppose there will always be in our profession. The only practical question is, have we the best method of selecting and training them. In some towns remote from the great centres, selection by the *vox populi* prevails; the elder practitioners who have attained the greatest repute with the public, relegating midwifery and minor surgery to their juniors, and practising as consultants at advanced fees.

I scarcely think this plausible method of selection a good one. The public is not a very trustworthy judge of medical skill, and, when left to its unaided instincts, is apt to make

favourites of men more remarkable for knowledge of the world than for knowledge of pathology. The London system, which gives the schools and large hospitals the key of the position, seems to afford a better security. Schools there must be; and these schools must have teachers. It hardly needs demonstration that the teaching will be best carried on by men who make it their life's work, and that both teachers and schools must in some way be connected with large general hospitals. Granting then the existence of medical schools, it can hardly be but that the school-teachers, selected in the first instance by their seniors, furnished with opportunities for exact study, disciplined by the continual presence of a watchful class of students, with a pathologist playing Minos in the background, and, finally, introduced into practice by men of their own school, who have had ample means of gauging their merits, should be accepted as the natural consultants of the profession. Some school-men, no doubt, prove failures; but the failures are easily recognised, and are treated as such; while unmerited success is hardly possible through connection with a school.

It seems, further, not illogical to assume that the officers of the great special hospitals, even without the addition of a school, are likely to become eminently qualified to advise in their respective departments; and these two classes, the school-men and the special-hospital men, with a few individuals whose independent scientific work has won professional recognition, are, in fact, the London consulting body. By a salutary regulation of the leading hospitals, the consulting body is brought under the disciplinary rules of the higher grades of the London colleges; but the colleges, as such, no more *create* consultants than the bench of bishops makes parish clergymen.

The weak point in the London system, as I pointed out in my former letter, is the money-qualification necessitated by the present state of remuneration, which deters many able men from competing for school positions.

It is also much to be regretted, assuming that a general complaint is founded in fact, that the bounds of consulting practice are so laxly regulated, and that many, even leading, consultants are found to use their position to acquire what is virtually a good general practice. I regard this dabbling by consultants in general practice as an offence, and in a leader a grievous offence, not because it sacrifices an imaginary dignity (I see nothing undignified in general practice) but because it destroys the confidence which every man in the profession should be able to feel—that in procuring his patients the benefit of a second opinion, he runs no risk of seeing them taken from his charge.

The maintenance of a proper standard of consulting fees is probably the most efficacious remedy against this "dabbling." A consultant whose lowest fee is five guineas, is not very likely to be summoned to frequent attendances without due cause; one whose fee is ten or twenty, still less likely. The senior men, if their own practice is settled on a satisfactory footing, will have little difficulty in keeping their juniors in order.

I am, Sir, &c.,

January 15,1884. Z.

[To the Editor of the Medical Times.]

SIR,—I think "M. D." misunderstands both the present and the past relations of consultants to general practitioners, and is fostering an imaginary grievance. In the past there was a marked *social* distinction between the physician and the apothecary; the former was a graduate of a university, usually a man of learning and culture, a gentleman, and associating with persons of rank; the latter was a tradesman, and though often enjoying a large amount of public esteem and confidenee, occupied an altogether different social level. All this is a thing of the past, but there still lingers in the popular mind a traditional respect for the title of physician; hence the eagerness of Licentiates of the College of Physicians to style themselves physicians on the door-plates, window blinds, bill heads, bottle labels, &c. These are the men to whom has descended the dimmed glory of that ancient and honourable name.

But though the older physicians were generally distinguished as a body of learned men which produced many eminent workers in various branches of science, there can be no doubt that they possessed a very moderate share of clinical experience or practical acquaintance with disease, and were, as a body, inferior to the apothecaries in strictly professional knowledge. At the present time, on the contrary, consultants are those who have prepared themselves for special lines of practice by prolonged study of certain departments of disease; and it is only by virtue of their superior knowledge, acquired in almost all cases through the opportunities afforded by hospital appointments, that they hope for the confidence of their professional brethren and of the public. No doubt, general practitioners nowadays are superior in general attainments and professional knowledge to their predecessors the apothecaries, but it is certain that this advance has not kept pace with the vast strides that have been made in the progress of medical science, more especially by the development of special branches. The present curriculum barely suffices to give students a groundwork of general information, which, unless supplemented by special studies in every department, opportunities for which are incompatible with the duties of general practice, cannot suffice to fit them to deal adequately with many disorders which they must meet with in practice. The fact is, that so far from there being no difference between consultants and general practitioners, there never was a time when this distinction was better defined or more clearly justified.

I should be glad to see senior consultants raise their fees, as it would tend to increase the amount of practice done by middle-aged men. It is very doubtful if it could benefit the juniors, as we have the experience of the bar, at which the rule of raising fees is rigidly enforced, and the seniors are constantly removed by promotion; yet junior barristers are supposed to have quite as bad a price as junior consultants in medicine and surgery.

After all, I do not think the latter have much cause to grumble. There are infinitely more means of making money open to them than there were a few years ago: the appointments of insurance companies, sanitary authorities, and other public bodies; the large sums paid for medical writing, teaching, lecturing, &c., forming in the aggregate a very considerable amount to be distributed; and, lastly, the possibility of obtaining a moderate amount of practice at a comparatively early age, by paying attention to a special subject. It is somewhat arrogant of anybody to pretend to advise young men as a class; there are so many circumstances to modify each case, that such general advice becomes useless when applied to individuals. I imagine young men will moreover continue, perhaps not universally, to disregard the warnings of their seniors, who are, perhaps, a little apt to exaggerate their own early difficulties and the exceptional character of those abilities which enabled them to overcome them.

I am, Sir, &c.,

January 14, 1884. MEDICUS.

[To the Editor of the Medical Times.]

SIR,—If the few well-known leading consultants read the letter of "M.R.C.P." in your impression of January 5th, with the table of fees arranged so pleasantly for juniors, I think they would have exclaimed, "Audi alteram partem!" I am as anxious as anyone to see the "leaders" of our profession raise their fees, but, as matters stand at the present time, juniors must be reasonable. Were any great difference made in the scale now in use, it would cut off three distinct classes of patients from the consultants in question. First, there is the patient who does not feel ill, but is still "not quite up to the mark," and who, therefore, thinks he will call upon the physician he has been in the habit of consulting for, perhaps, years. He tenders his guinea, as he would do on several occasions should it be necessary to continue the consultations. Next, there is the class of invalids—mostly ladies—who, although not ill enough to have a constant attendant, nevertheless, desiring the best advice obtainable, like to be visited, from time, by one of the leading consultants, and who willingly gives the ordinary fee of two guineas. Thirdly, there is another class of patients most lucrative to the consultant, viz., those who are wealthy and, becoming acutely ill, wish to have in consultation with the

regular medical attendant their favoured physician once or twice daily until convalescence is established, gladly giving two guineas each time. I believe that if the fees are greatly raised these patients will be quite taken away from the foremost consultants, for although a patient will, with pleasure, give a guinea for advice at a physician's house, he will hesitate before giving three times as much, and it would be the same with patients who desire to be visited at their own homes. These remarks do not apply to those who come from a distance to London specially for an opinion, as, of course, they would give whatever fee was asked.

Now, the result of this loss to the above consultants would be exactly what "M.R.C.P." and your other correspondents desire, viz., that the juniors would have a chance of gaining a greater number of patients. But, as a matter of fact, I consider the leading consultants cannot afford to raise their fees, as it would clearly diminish their incomes. It is, however, quite certain they would do it if they could, and since it is not done, the inference is that, owing to the immense competition in our profession, they do not have, as a rule, more work in the twenty-four hours than they can undertake. It is very easy for any physician to refuse work should he have more than he is able to accomplish, but we all know how difficult it is to secure it.

Finally, we must remember that "life is short," and that the foremost of our profession only fall into the swing of real consulting work when they are fairly advanced in life, and have, therefore, at the best, but comparatively a short time in which to make up for years of unremunerated labour, and to provide for the future and their families. How poorly the latter is done the wills of medical men often prove! If the consultant happen to be a baronet, with a son, he must work all the harder, for he has not only to provide for his own future, with possibly failing health, but he must endeavour to leave behind him something substantial wherewith to keep up the baronetcy.

If the younger consultants are disappointed with their lot they can follow your advice and strike out another line for themselves; but I think a great deal of the disappointment which prevails is due, as pointed out by "A Contented Consultant," to increasing expenses—expenses which were probably not fully considered at the outset of their career.

My own opinion is that, as our education has made such rapid strides within recent years, and so many men take the very best qualifications which can be had, the distinction between consultants (so-called) and others will gradually die out, although a few men, through their own talent, will always be more sought after than the others.

All who are intimately acquainted with young consultants know how thankful they are, speaking generally, to do anything which comes within their reach, whether or not it strictly belongs to their particular province. Such must often be distasteful to them, but they cannot always help it, for they, as others, must live. But, clearly, this should not be. If, therefore, there is to be a change, we must begin at the source of the evil; physicians and surgeons attached to hospitals must be sufficiently paid for their work. This would allow them to wait patiently for their turn of good fortune, whilst it would enable consultants in the first rank to considerably raise their fees, for, before attaining to that eminence they would have been adequately remunerated for services rendered.

Should anyone desire to perform his hospital work from a purely charitable spirit he could, at any time, refuse his salary.

I am, Sir, &c.,

Jan. 15, 1884. X.

[To the Editor of the Medical Times.]

Sir,—The plethora of consultants is, I think, more apparent than real. That a larger number of so-called consultants exists to-day than existed, say, 20 or 30 years ago, I quite admit, but London and our other big cities have grown enormously in the interval. This plethora, however, is largely the result—and not a bad one—of the improved education which the young medicus now gets, and the disparagement (if there be any) in the term "general practitioner" is the natural outcome, on the one hand, of the older and very insufficient education which was once considered good enough; and, on the other hand, of that deterioration (by no means confined to "G. P's.") which all men scientifically undergo who are not constantly keeping themselves abreast of the times. And how can it be otherwise? Nine-tenths of the ordinary students qualify as soon as they possibly can, and disappear from the hospital; that is, they give up all further systematised study of their profession. Can it be wondered at that, after a few years in a quiet town or country place as general practitioners, they should become a little rusty on theoretical and scientific questions, and a little less "well up" in the newer methods and signs of diagnosis than the generation which is rising and pushing on ever with increasing energy and improving opportunities. How specially true is this of the operating surgeon! Constant practice can alone "keep the hand in" and increase its natural cunning! The remaining tenth of the students—including probably among them the best educated and most energetic of the whole number—continue at their hospital for, it may be, years beyond the regulation period: they hold the resident appointments, and fill the minor posts at the schools. Many of these, not having private means, then settle down in general practice, and, if a medical man's life can be called happy, they are happy and even successful. They are fully appreciated by their patients and by the "heads" of the profession. The remainder become the "consultants," about whom some of your correspondents speak so slightingly. If they knew the "grind" which is necessary to success, they would hardly envy them; they would certainly not "sit upon them" so unmercifully—they might even "employ" them. The "heads" of the profession are the picked men of those "consultants," and stand in the same relation to them that a sound well-educated general practitioner does to the immature product of the curriculum pure and simple. It is very desirable that there should be a goodly number from which to select, and in eight cases out of ten it will be found that the "weaker go to the wall." I fail to see that there is a plethora such as you suggest: the supply is regulated by the demand. I think nothing will so conduce to the dignity and social status of the profession as the attempt to keep up this supply. Why should not every man who enters the profession become a "consultant?" I have briefly sketched out the plan that must be adopted, and the additional years which have to be devoted to study. The profession will not be any the worse for it, and I feel sure the public will gain. The separation of the drug business from the practice of medicine would be one of the first results; while the numerous hospitals springing up all over the country would thus secure able and well educated men for their staff appointments.

The "heads" of the profession could then be chosen from the whole profession, rather than, as at present, from the minority, and might be called "consultants" (provided always they limited themselves to consultation cases), while the rank and file might adopt the titles at present in use, "physician" or "surgeon," in accordance with the class of practice they felt most congenial to their tastes or abilities. This would be a practical solution of the situation.

I am, Sir, &c.,

Chirurgicus Ambulans.

London, *Jan.* 14, 1884.

"THE MEDICAL TIMES."

[To the Editor of the Medical Times.]

Dear Sir,—You will, I hope, pardon me if I venture to take exception to one or two points in your article treating, on the 5th instant, of the new departure made by this Journal. After praising in well-deserved terms the admirable management of the *Medical Times and Gazette*, first by Sir Spencer Wells, and next by the late Dr. Druitt, you are kind enough to say that the "aims impressed upon the Journal by those able and successful editors have been consistently followed by their successors." But you do not name any of those successors, and the term used appears to me vague, and likely to give the idea that several or many gentlemen occupied the editorial chair between the resignation of Dr. Druitt and the end of last year. In fact, there were during that period only two editors: my friend the late Dr. F. C. Webb, who imme-

diately succeeded Dr. Druitt, and myself. Dr. Webb felt great pleasure in the management of the Journal, and edited it with success till the day of his death in 1873; and it would, it appears to me, have been a graceful act to have named him as one of the former editors, and an act that would have been grateful to his friends. As to myself, I know that I considered it a not light honour to be asked to edit such a journal as the *Medical Times and Gazette*, and it was only after much hesitation, and with great diffidence, that I decided to accept the office. For all the generous help and consideration that I received from the profession throughout the term of my editorship, I was, and am, deeply grateful; and owing to that help, and the ability of my co-workers, I was, I venture to hope, enabled to be of some little service to my professional brethren, and to the well-being and advancement of the science and art of medicine. Therefore is it, Sir, that I confess that it would be pleasant to me to see the fact that I was editor of the *Medical Times and Gazette* for close upon ten years, put on record before the history of that journal is quite overshadowed by the renewed life and vigour of the *Medical Times*.

I am, dear Sir, yours very faithfully,

WM. CHOLMELEY.

NEW INVENTIONS & IMPROVEMENTS.

CAFÉ VIERGE.

THIS is a very concentrated essence of pure coffee, prepared in the laboratory of Messrs. Allen & Hanburys. Its main purpose, of course, is dietetic, and from it can be prepared a cup of coffee which in flavour is almost equal to that made from freshly-roasted berries; but it would no doubt also prove very useful as a therapeutical preparation, in those rare emergencies in which strong coffee is indicated.

MEDICAL NEWS.

PORTRAITS OF DR. JENNER.—An evening paper informs us that the medical faculty have been endeavouring to discover original portraits of Dr. E. Jenner. Two by Northcote, R.A., have come to light. One is in the possession of the Plymouth Medical Society; the other is in the keeping of the Devonport Medical Association.

DEATH OF DR. GARRINGTON, OF PORTSMOUTH.—Dr. Garrington, who died at Portsmouth on the 7th inst., aged 79, was the senior magistrate on the Portsmouth bench, an ex-mayor, and for many years the borough coroner.

FIRE AT A LUNATIC ASYLUM.—A fire broke out in the laundry of the Cornwall Lunatic Asylum, at Bodmin, on Friday week, creating great alarm. Fortunately it was discovered in time, and, by the strenuous exertions of the officials and the members of the brigade, the flames were got under without any necessity having arisen to disturb the 800 inmates.

THE PARKES MUSEUM.—At the meeting of council of Parkes Museum of Hygiene on January 8th, Sir James Paget, Bart., F.R.S., was elected a life member, and Mr. H. A. Darbishire, F.R.I.B.A., an annual member.

THE LATE THOMAS RIVINGTON WHEELER, F.R.C.S.—Mr. Wheeler, whose death recently occurred suddenly at Ramsgate, had for some years past acted as secretary to the Court of Examiners of the Society of Apothecaries, and also as secretary to the Board of Examiners in Arts. He was well known in the ranks of the profession, amongst whom his attainments and amiability of character secured him the friendship and esteem of not a few, and his loss will be sincerely felt and recognised. Dr. Peregrine has been elected by the society to fill the vacancy thus occasioned.

THE CHOLERA IN EGYPT.—A telegram from Alexandria, dated the 15th, states that no cases of cholera have been officially notified in Egypt since December 26.

ROYAL COLLEGE OF SURGEONS.—At a meeting of the Council, held on the 10th inst., the following member was elected to the Fellowship, viz., Mr. Arthur Colling Brownless, of Melbourne, Victoria, his diploma of membership bearing date March 26, 1841.

THE HOSPITALS ASSOCIATION.—The inaugural meeting of this Association will be held, by permission of the Lord Mayor, at the Mansion House, on Friday the 1st February, at 3 o'clock. His Lordship will preside. Further particulars will be shortly announced.

LIVERPOOL MEDICAL INSTITUTION.—At the Annual Meeting, held Thursday, January 10, 1884, the following list of Officers and Council, and Microscopical Committee, was adopted. Those marked * did not hold the same office last year. President, *Dr. Robert Gee; vice-presidents, Dr. W. Macfie Campbell, Mr. Rushton Parker, *Dr. J. Wallace, *Dr. J. H. Wilson; honorary treasurer, Dr. James Barr; honorary general secretary, Dr. F. Pollard; honorary secretary ordinary meetings, Mr. Frank T. Paul; honorary librarian, Dr. Burton; council, Dr. Alexander, Dr. Archer, Dr. Carter, Dr. T. Clarke, Dr. Glynn, *Dr. Grimes, *Dr. Imlach, Mr. McCheane, *Dr. R. F. Owen, *Mr. R. N. Pughe, *Mr. T. Shadford Walker, *Dr. Young; microscopical committee, Dr. Alexander, Dr. Braidwood, Dr. Briggs, Dr. Glynn, Dr. Grossmann, Dr. Hicks, Dr. McClelland, Mr. Newton, Mr. Rushton Parker, Mr. Frank T. Paul, Dr. Rich, Dr. Whitford, and Dr. W. Williams.

PRESENTATION.—A testimonial, in the form of a handsome operating case, was, on the 10th inst., presented to Dr. G. H. Darwin, of Manchester, by friends residing in St. George's Parish, in that city, "as a token of their esteem."

ENTERIC FEVER AT ABERDEEN.—A small epidemic of enteric fever has broken out in the better parts of Aberdeen, which is attributed to infection by milk. Sixteen cases have occurred, two of which have proved fatal.

WARWICK UNION.—Dr. Bradley has resigned his appointment as Poor Law Medical Officer in the Leamington District. The area of the district is 12,449 acres; the population, 27,975, and the salary of the post £200 per annum.

MILK ADULTERATION IN DUBLIN.—A discussion arose last week, at the North Dublin Union, on milk adulteration, when it was stated by Dr. Norwood that fines imposed are paid out of a subscribed fund by dairymen—the conclusion being that more effectual punishment is necessary. Mr. North's suggestion that a personal penalty should be substituted in gross cases will have the sanction of public opinion, and it is well to find a guardian prepared to propose the heroic remedy that appears to have become inevitable in the circumstances.

UNIVERSITY OF EDINBURGH.—The matriculation returns for the past year have now been made up, and again show a very satisfactory increase. The aggregate number of students matriculated during the year in the Faculty of Medicine was 1,781, of whom 682 were from Scotland, 620 from England, 33 from Ireland, 123 from India, 264 from the different British colonies, and 59 from foreign countries. These returns point out the very satisfactory increase of students coming from our colonies. During the year, 31 students took the degree of Doctor of Medicine (M.D.), and 189 the double degrees of Bachelor of Medicine and Master in Surgery (M.B. and C.M.), the proportion of students on the register proceeding to graduation being 1 in 8. A Lectureship on Diseases of the Eye has been instituted in the University, and Douglas Argyll Robertson, M.D., appointed lecturer. This course was given with very successful results during the summer session. During the past year the following additions to the endowments of the University have been made:—A capital sum of 1,500*l.* has been given by Frederick John Mouat, M.D., of the Local Government Board, London, and formerly Professor of Medical Jurisprudence in the University of Calcutta, for the foundation of a scholarship—to be styled "the Mouat Scholarship"—in the practice of physic in connection with the class of practice of physic in the University. The late Miss Dick, of Edinburgh, bequeathed the moiety of the residue of her pro-

perty, estimated at about 10,000*l.*, to trustees, under certain conditions, for the purpose of founding a Professorship either of Comparative Anatomy or Surgical Anatomy (whichever the trustees may consider most desirable in the interests of Medical Science) in the University of Edinburgh. The several departments in the University New Buildings are now occupied and in full operation. They comprise all the classes in the Medical curriculum, with the exception of those of Botany and of Natural History—the former remaining attached to the Royal Botanic Gardens, while the latter (owing to the proximity of the Natural History Museum) is accommodated in the Old University.

Society for Relief of the Widows and Orphans of Medical Men.—A Quarterly Court of the Directors of the Society was held on Wednesday, January 9th, at 5 p.m., in the rooms of the Roy. Med. Chirg. Society, 53, Berners Street, Mr. Charles Hawkins, J.P., in the chair. The resignation of two members were accepted; the deaths of two reported, and two new members were elected. The Treasurer informed the meeting that a Christmas present had been made to the widows and orphans in December last, amounting to 307*l.* Grants to the extent of 1,241*l.* were made to 58 widows, 5 orphans, and 3 orphans on the Copeland Fund. The expenses of the quarter were 64*l.* One fresh application was received from a widow, and a grant made.

Faculty of Physicians and Surgeons, Glasgow.—At a recent meeting of the members of the Faculty of Physicians and Surgeons, Glasgow, it was resolved that after the Sessional year the Faculty would cease to grant single qualifications, unless the candidate already had a medical qualification, but that it will continue to grant the double qualification as heretofore, with the College of Physicians, Edinburgh. Negociations are now going on with the College of Surgeons, Edinburgh, so as to include it also in the granting of the double qualification—"Tria juncta in uno."

Finsbury Dispensary.—The biennial festival of this old established dispensary was celebrated on Monday evening, at the Holborn Restaurant, under the presidency of the Right Hon. The Lord Mayor, M.P., supported by the Sheriffs of London and Middlesex, Mr. Barclay Field, treasurer, Mr. Richard Moreland, honorary secretary, Dr. Domett Stone, one of the physicians to the institute, and upwards of 100 other gentlemen. From the 104th annual report, which was circulated during the evening, it appears that the number of new patients in the year 1883 amounted to 13,719, which exceeds by 944 that of the previous year, and is the largest number yet relieved in any one year by this dispensary. The number of attendances was 32,619; the number of visits by the Medical Officers to patients at their own homes 3,570, making a total of no less than 36,382 consultations in the year. During the evening subscriptions to the amount of £510 were announced.

Royal College of Surgeons of England.—The following gentlemen passed their primary examinations in Anatomy and Physiology at a meeting of the Board of Examiners on the 8th inst., and when eligible will be admitted to the pass examination, viz.:—

M. Eleyatamby, of the Ceylon School.
E. L. Fox, of the University of Cambridge.
R. B. Robson, T. Morton, and H. Renny, of the Newcastle School of Medicine,
A. L. Williams, of the Liverpool School of Medicine.
C. Mortlock, of St. George's Hospital.
W. E. Morgan, of St. Bartholomew's Hospital.
J. Good, of Charing Cross Hospital.
J. B. Webb and H. A. Spencer, of the Bristol School of Medicine.
J. W. Barrett, of the Melbourne University.
W. S. Cox and A. O. Balshaw, of the Manchester School of Medicine.
F. W. Gordon, of the Dublin University.
A. R. Macmillan, of the Edinburgh University.

Eight candidates were referred to their studies for three months.

The following gentlemen passed on the 9th instant, viz.:—

P. P. Baly, of the Birmingham School of Medicine.
H. Anderson, of the Belfast School of Medicine.
A. W. Riddell, of the Bristol School of Medicine.
S. L. Davis, of the Bristol School of Medicine.
F. C. Servaes, of the University of Cambridge.
E. N. Nason, of the University of Cambridge.
C. Nicholson, of the Leeds School of Medicine.
F. Jubb, of the Leeds School of Medicine.
H. Massey, of the Dublin School of Medicine.
F. S. P. Lely, of the Liverpool School of Medicine.
C. E. Dodd, of the Liverpool School of Medicine.
W. B. Caley, of the Liverpool School of Medicine.
S. Hawarden, of the Manchester School of Medicine.
H. C. Coe, of the University of Harvard.
A. King, of Charing Cross Hospital.
C. J. Deyns, of Middlesex Hospital.
W. B. Colquhoun, of Guy's Hospital.

Six candidates were referred for three months, and one for six months.

The following gentlemen passed on the 10th instant, viz.:—

P. E. Barber and W. H. Beaumont, students of the University of Cambridge.
Percy Rose, W. P. Le Feuvre and F. W. Turtle, of Guy's Hospital.
E. S. Smith, of St. Mary's Hospital.
C. T. Green, of St. George's Hospital.
E. A. Lubbock, of the London Hospital.

NOTES, QUERIES, AND REPLIES.

PROVINCIAL HOSPITALS.

TO THE EDITOR OF THE MEDICAL TIMES.

SIR,—Will you kindly permit me to inquire through your columns, what is done in provincial towns having hospitals, where, either there is no resident physician, or none willing to undertake active work at the hospital? The number of towns so circumstanced must be increasing in these days, in which the facilities of communication tend to draw consultative practice to London. Under such circumstances, are general practitioners invited to undertake the medical charge, and under what titles? And, in such cases, are the branches of medicine and surgery still maintained apart? Or are they merged together, as I believe to be commonly the case in French hospitals? If any of your readers will oblige me with a statement of their experience, addressing their letters as below, I shall be greatly obliged, as the subject is of practical importance to us here,

Yours faithfully,

St. Mary's Rectory, Colchester, JOHN W. IRVINE.
January 12.

AN ENQUIRY.

TO THE EDITOR OF THE MEDICAL TIMES.

SIR,—Could you kindly give me information on the following subject:—Is a district Medical Officer compelled by law to obey a magistrate's order to examine and report on a supposed lunatic living in another Medical Officer's district? Your advice will oblige.

Yours faithfully,

13th January, 1884. POOR-LAW MEDICAL OFFICER.

MODERN OPERATIONS FOR CATARACT.

The Lettsomian Lectures Delivered at the Medical Society of London.

By R. BRUDENELL CARTER, F.R.C.S.,

Ophthalmic Surgeon to St. George's Hospital.

Lecture II.

The division of my general subject to which I propose to direct attention this evening is that of the so-called "maturity" or "immaturity" of cataracts; and the progress which has been made in the surgical treatment of those which must be included under the latter denomination.

The word "maturity" as applied to cataract, must be understood to mean that the degeneration of the lens tissue has extended to the most superficial layers, those immediately adjacent to the investing capsule; and, in like manner, the word "immaturity" conveys that these superficial layers are not yet involved in the degenerative process, and that they retain some of their original characters, notably their transparency, their viscidity, and their adhesion to the capsule, either unimpaired or with only slight impairment.

When cataract is sufficiently advanced for any question about maturity to arise, the lens presents itself under one of two aspects. In the first of these it is blueish-white in colour, the whiteness not being uniform, but broken by lines, and the whole surface having an appearance between that of spermaceti, and that of an inferior opal, one which does not yield coloured reflections. In the second aspect, which is of comparatively rare occurrence, the surface is of uniform tint, and resembles that of bee's-wax, or brownish-yellow horn. In very exceptional cases of the latter class the colour is still deeper, ranging from dark brown to something which by a figure of speech may not unfairly be described as "black."

When any of the above mentioned appearances are met with, it becomes important to ascertain whether the opaque surface is in actual contact with the capsule of the lens, or is separated from it by a layer of still transparent tissue; and this question admits of being determined in a simple manner. With a moderately dilated pupil, we direct a pencil of light upon the eye, causing it to fall obliquely from the temporal side. If the opaque portion of the lens be in contact with the iris, except for the intervention of the anterior capsule, the margin of the pupil will cast no shadow upon the opacity. If, on the other hand, the iris be separated from the opaque portion by a layer of transparent tissue, the margin of the pupil will cast a crescentic shadow, the breadth of which will be proportionate to the extent of the separation.

Another test is afforded, especially in the white varieties of cataract, by the fact that the margin of the pupil is encircled, in all eyes, by a fine black line, which is generally lost to sight against the blackness of the aperture. When the aperture is no longer black, the fine black line becomes conspicuous, and especially so in persons with light irides and with any of the lighter coloured varieties of lenticular opacity. In such it is

not difficult to see, by the exercise of ordinary care, whether the black line is in close apposition with the opacity, or is separated from it by an appreciable interval.

When the operation of "flap-extraction" was the only one practised, the advantages of waiting for the complete maturity of cataracts were impressed upon surgeons by the unfavourable results of earlier interference; although it may be doubted whether the reasons of these unfavourable results were quite understood until after the custom of an early examination of the eyes operated upon was fully established. The reasons were, that in mature cataract the superficial layers of the lens were rendered visible by their opacity, and that they left the eye easily on account of the loss of their natural viscidity and of their natural adhesion to the capsule. Hence when the pupil appeared clear and black at the close of an operation, it was clear in reality; and, until this condition was attained, the residual cortical matters might be extruded by slight friction and pressure, so gentle as not to involve any great risk of rupture of the hyaloid membrane and consequent escape of the vitreous body. On the other hand, when a lens was extracted in an "immature" condition, the superficial transparent portion not only clung to the interior of the capsule, and could not be removed without much difficulty, but its presence in the eye was concealed by the very fact of its transparency, and might even remain unsuspected by the surgeon. In such cases, although the pupil would seem clear and black at the close of the operation, it would not be clear in reality, and, if the eye had been examined twenty-four hours later, when the residual lens matter had been acted upon by the aqueous humour, the pupil would have been found occupied by a quantity of disintegrated cortical tissue, swollen and rendered opaque by maceration. This material was apt to undergo proliferation and increase; and, at the same time, to excite acute iritis, which, when it occurred immediately after the large external wound of flap-extraction, was generally, or perhaps always, destructive to the eye. In other words, the only successful cases of the extraction of immature cataract by the flap-operation were those in which iritis did not occur, or in which it occurred in a degree sufficiently slight to be recovered from. The total thus constituted was not considerable, and the advisability of deferring operation until a cataract was fully "ripe" became an accepted principle of ophthalmic surgery. It was only by obedience to this principle that even the moderate measure of success, to which I referred in my first lecture, could with any certainty be commanded by the surgeon.

While such were the advantages of waiting for the maturity of cataract, the disadvantages of doing so, or rather the disadvantages to the patient of being compelled to do so, were of the most striking and obvious kind. The delay was always extremely irksome, and was often of far more serious consequence. In the case of comparatively poor people, cataracts often became sufficiently far advanced to interfere with the usefulness of vision, and to necessitate the abandonment of work, long before they were fit for removal. In other words, their presence often struck at the root of the means of living of an elderly person, who, but for them, might have continued to follow an occupation which afforded a comfortable maintenance. Deprived of this, brought into reduced circumstances, and left a prey to the most cruel anxiety, it could be no matter of surprise if the general health sometimes became so much impaired that its impairment would militate against the ultimate success of any surgical procedure; while, at the same time, the boon of restored sight, if such restoration were ultimately effected, was rendered of comparatively little value. An industrial connection had been broken, the vacancy occasioned by compulsory withdrawal from occupation had been filled up, and the restored sight did but enable the sufferer to see his or her pathway to the grave. Among people in better circumstances, also, the long tedium of waiting during the period of failing vision was often exceedingly depressing: and, notwithstanding the command of every comfort, it often interfered with sleep and with nutrition, and perceptibly lowered the powers of life. There would be, of course, the widest differences in these respects, differences depending upon temperament, or upon the intellectual or moral character of the individual; but there are few persons so endowed with fortitude and with hopefulness that slowly increasing blindness will leave their health or their spirits unaltered, or their powers of vital resistance unimpaired. In every class, therefore, it becomes an object of legitimate endeavour to abbreviate the period of waiting; and to restore the sight as soon as any operation can be undertaken with a proper degree of safety; while, in a certain proportion of cases, it even becomes justifiable to incur some amount of additional risk, at all events with one eye, in the hope of obtaining a speedy good result. For example, I was consulted, a few years ago, by a lady who held a superintending position in a large mercantile house—a position which required the exercise of much visual discrimination, and in which she was liberally paid. Her lenses became slightly turbid, just in a sufficient degree to interfere with her efficiency; but the turbidity was of such a character that, in all probability, ten years might have elapsed before the cataracts could be called mature. Her employers valued her services very highly, and were willing to wait any definite or reasonable time; but they could not have waited for the maturation of the cataracts, and hence the question arose whether anything could be done for her without delay. I thought it justifiable, by methods which I shall presently describe, to incur the risk of operating on one eye only; and, when this one had been completely restored, I operated upon the second in its turn, and with a like result. The patient has retained her position, and is able to fulfil all its requirements. I remember the time when no such operations could have been undertaken, by any methods then practised, with a reasonable expectation of success; and, as there is no such thing in life as an isolated case, the grievous loss of income and of occupation from which this lady was rescued must have befallen many who were similarly circumstanced in former years. It would be easy to cite many examples of a similar kind; but the position sought to be established is almost self-evident, and it would be little better than a waste of time to dwell upon it.

In order to determine the class of cases in which early operations may be undertaken, it is necessary to reflect on the various physical conditions which the lens may present As life advances, and old age steals on, the lens undergoes a process of hardening, which is most pronounced in the central portions, those most remote from the sources of nutrition; and at the same time it gradually assumes a yellowish or a brownish tint. These changes seem to be of universal occurrence, and the central hardening serves to establish a difference, which did not previously exist, between the "nucleus" and the "cortex;" but neither the hardening, nor the discolouration which attends it, would of themselves interfere seriously with vision. The nuclear hardening, however, seems in some cases to produce a physical separation between the central "nucleus" and the layer of "cortex" which immediately surrounds it; this separation not at first being general, but affecting certain portions only, and leading to the molecular disturbance of the cortical elements which are thus deprived of their natural continuity with the structures beneath. The elements which are so

affected become opaque, and tend to pass into a state of fatty degeneration, which ends in complete liquefaction. The ultimate fibrils of which the lens tissue is composed are themselves built up into wedge-shaped sectors, having their bases towards the equator and their apices towards the poles; while the fibres which form the apices of the sectors in front, and which there extend to the anterior pole of the lens, are those which, on the posterior aspect, barely overlap the equator. It follows from this distribution that, when a layer of lens tissue becomes opaque, the opacity does not advance uniformly, but in sectors; and the result is that, when cataractous change invades the eye of an aged person, we see the uniformity of the pupil broken by wedge-shaped striæ of opacity, having their bases concealed beneath the iris, while their apices approach the centre. The chief differences which occur in the development of senile cataract depend upon the proportions which the nucleus and the cortex bear to one another, or, in other words, upon the depth within the lens at which the detachment of the softer cortex from the harder nucleus commences. If this separation occur at only a small depth below the capsular surface, so that the cortical layer is thin, the nucleus will necessarily be of larger bulk than in the cases in which the separation occurs more deeply, leaving a comparatively thick layer of superficial material to undergo the peculiar cortical degeneration, and a nucleus of small magnitude inclosed within. The thinner the cortical layer, the more slowly, as a rule, do the changes which produce opacity make progress, and the finer and smaller are the striæ in which the opacity is first apparent. The converse also holds good; insomuch that, when the cortex is thick and abundant, the opaque lines of cataractous invasion are broader and more conspicuous, and they tend to increase, to coalesce, and to invade the whole surface of the lens, with much greater rapidity. In the determination of the sometimes difficult question, at what stage of the development of cataract the fact of its existence should be made known to the patient, it is always necessary to bear in mind that, when the striæ are fine and small, and therefore developed only in a thin and superficial layer of lens substance, their increase and maturation must not be expected to occur nearly so soon as when they are broad, and developed in a thicker layer. In cases of the former class, we often see the state of the lens, especially in very aged persons, remain with little manifest change for long periods; while, in those of the latter, the increase of the opacity is not only conspicuous to external observation, but forces itself upon the attention of the patient by the rapid deterioration of sight which it occasions.

Whether the hard nucleus be large or small, and consequently whether the enveloping layer of cortex be thick or thin, the opacity commences in that portion of the latter which is adjacent to the nucleus, and only afterwards invades the more superficial portion, or that which is adjacent to the lens capsule. The opacity increases by an increase in the length and breadth of the striæ, by a corresponding increase in their thickness, by which they approach the capsule, and by their coalescence as they meet. Until the opacity has reached the capsule, the lens displays something of its original striation; but, when or soon after this stage has been attained, the opaque cortex commences to break up and liquefy, to become the seat of calcareous or of fatty deposits, and to lose all trace of structure; while the nucleus, in such cases, no longing receiving the support which the previous coherence of the cortex afforded it, sinks to the bottom of the capsule, and may be seen, by adequate illumination, to change its place with changes in the position of the eye. In a degeneration which is gradual in its course no exact definitions of the successive stages can be framed; but there is a certain amount of convenience in describing a cataract as "incipient" before it interferes seriously with vision; as "progressive" when it has fairly invaded the area of the undilated pupil; as "mature" when the opacity has reached the capsule; and as "over-mature" when the natural striation of the cortex is beginning to disappear. The distinction between "hard" and "soft" cataracts, as applied to those of aged people, is less satisfactory as a matter of phraseology, because every cataract is both hard and soft, or is composed of a hard nucleus with a softer investment. The words express, however, although in a clumsy sort of way, whether the nucleus be large or small, and this is a matter of the greatest practical importance. A nucleus of large size adds much to the difficulties of the surgeon, and in a corresponding degree diminishes the prospects of a favourable issue.

The physical conditions, then, with which we have to deal in cataract, may be summarised somewhat as follows:—There must always be a hard nucleus, of variable size, and this must always be enveloped in a layer of cortical substance, the thickness of which varies inversely as the size of the nucleus. In "progressive" cataract the cortical substance may be opaque, or of an opacity interrupted by still transparent lines, in the laminæ immediately surrounding the nucleus; while it is transparent in the more superficial laminæ which separate the opaque portions from the capsule. When this is so, the still transparent laminæ retain a viscidity and coherence which those invaded by opacity have lost. At this stage it is not uncommon for the bulk of the lens to be increased, as if by the imbibition of fluid, so that the iris becomes pushed forward towards the cornea, and the depth of the anterior chamber is diminished. In more advanced, or "mature" cases, the opacity will have reached the capsule, and the whole of the cortex may be reduced to a pulpy consistence, still showing some trace of sectorial divisions and of fibrillated structure, but with little or no adhesion either to the capsule or to the nucleus. By this time, generally speaking, the lens will have returned to its normal dimensions. At a still later period, all traces of sectorial or fibrillated structure will disappear, and the capsule will contain a milky or turbid fluid, and will perhaps be mottled by dots of calcareous deposit, while the nucleus may be discovered floating loosely within. Where surgical interference has been withheld, and time and opportunity afforded, it has sometimes happened that a good deal of the fluid cortex has ultimately undergone absorption, and that some amount of vision has been restored. The nucleus, in such cases, has either retained its transparency, or its small size has removed it from the axis of vision.

Our predecessors were taught, by the experience of the days of flap extraction, that while it was advisable to wait until a cataract was mature, no advantage was to be derived from waiting too long. The condition of over-maturity, indeed, was decidedly unfavourable to success; partly, it may be, because it would usually be associated with other senile changes, partly because the completely degenerated cortex, when liberated from the capsule, seemed sometimes to act as a septic irritant, and partly because the calcareous particles which were often present were not easily removed from the eye, and were apt to become mechanical irritants if they were left behind. The condition which was regarded as most favourable was that which has been already described as maturity, in which the opacity was in contact with the anterior capsule, but in which it still displayed indications of a radiating striation. The same description of the most favourable condition must be given even now; but the practical question is whether the difference between this, and something which falls short of it, is sufficiently marked to be, in the majority of cases, worth waiting for? It may be laid down as a general principle that a cataract

should not be touched so long as the patient is able, even with some difficulty and by the aid of artificial dilatation of the pupil, to follow his or her usual occupation, or so long as the final issue can be awaited with cheerfulness and courage. When these conditions can no longer be fulfilled, when the habitual pursuits have to be abandoned, or when sleep, appetite, and digestion are disturbed, it becomes time to inquire whether something cannot be done to afford relief. In a considerable number of instances the answer may be in the affirmative.

As far as I am aware, the first step in this direction was taken by von Graefe, as one of the results of his method of modified linear extraction. In a large proportion of cases, senile cataract invades both eyes, but advances more rapidly in one of them than in the other; and von Graefe announced that, after having successfully extracted a mature cataract from one eye, he was accustomed to proceed boldly with the other, and to operate upon it at a much earlier period than would formerly have been thought desirable. His example was soon followed by other surgeons; and, both in respect of the choice of methods, and of the conditions most favourable to success, a large amount of experience was speedily obtained. The general result of this experience may, I think, be fairly expressed by saying that, when the physical or moral conditions already referred to are fulfilled in such a degree as to render operation desirable, the prospects of success will be at their highest in cases of small nucleus and abundant cortex, and will be greatly promoted by a return to the original method of Mooren, that is to say, by performing iridectomy as a preliminary operation, some weeks before the actual extraction of the lens is attempted. Still more, I venture to think, will depend upon the careful observance of many small details in the conduct of both operations, and also upon the care and knowledge with which, in the event of complications arising, both the local and the general treatment are conducted. As a preliminary to my endeavour to point out the means by which a favourable issue is frequently to be obtained, it will be convenient to sketch, in brief outline, that method of extracting the mature cataract, by a single operation, which, founded upon the lines laid down by von Graefe, has in some measure been modified by the work of other surgeons. It is not my intention to describe mere paper or diagrammatic variations, impossible to be carried out with certainty in practice, but only the general results which have been obtained, and the broad principles on which they are founded. In many instances, I think, the slight modification introduced by some single operator is to be regarded as personal to himself, perhaps as advantageous for the requirements of his particular hand, for his particular point of dexterity or of the absence of it, but not as having any special applicability to others. In manipulation, as in observation, there is distinctly what is called at an observatory "the personal equation" of each worker, by which his observations are to be reconciled with those, slightly different from them, made by others; and I am quite sure that much invention of instruments, and much modification of operative detail, is in like manner personal, the mere expression of the skill, and sometimes it may be of the awkwardness, of those with whom such variations originate. It is from this point of view that I approach my subject, and it is on this ground that I shall avoid dwelling upon many points which some have thought important, but which seem to me to be trivial.

When modified linear extraction was first introduced, it was the custom of most surgeons to dilate the pupil prior to the operation, and to do so by the repeated application of atropine. The idea was that the lens would thus be suffered to escape more easily, and much stress was laid upon such a manner of making the first incision that the aqueous humour should be suffered to trickle away slowly and gradually, by which course the pupillary dilatation was maintained. At this period, one of the most frequent and most troublesome complications was the entanglement and adhesion of the iris at one or both of the angles of the wound, an accident which, at the best, was followed by drawing up of the pupillary aperture to a point above the centre of the cornea, and which, at the worst, led on to destructive inflammation. Of late years, the separation of the active principle of the Calabar bean has given us, in the shape of eserine, a drug of very great value in many ocular maladies; and not the least of its uses depends on its power of producing contraction of the pupil, by which the iris may be drawn out of the angles of the operation wound, and pulled well down into the anterior chamber. When once a piece of iris is cut out, and the continuity of the sphincter of the pupil is destroyed, there is nothing left which opposes any resistance to the exit of the lens; and the benefit which was once supposed to be obtained from atropine was probably in a great degree imaginary. At any rate, the loss of this benefit is very cheaply purchased by the gain of preventing entanglement of the iris; and so, at the present day, the instillation of eserine, as a preliminary to iridectomy, has become almost universal. As in the case of atropine, the tendency of the pupil to return to a state of medium dilatation on the evacuation of the aqueous humour may to a great extent be checked by causing this evacuation to occur very slowly, but this is not a matter of much practical importance. Even if the pupil return to medium dilatation at the time of the operation, the effects of the eserine will speedily reassert themselves, and the iris will be kept well away from the wound angles before it can possibly become adherent to them. During the progressive stage of cataract, moreover, when the iridectomy is often required as a preliminary operation, and especially in cases of small nucleus, it is, as I have already stated, not uncommon for the lens as a whole to be enlarged by swelling of the cortex as a consequence of the imbibition of fluid during the degenerative process. When this occurs, the iris is pushed forward and the anterior chamber narrowed; and, in these circumstances, the pupillary contraction brings the iris between the lens and the entering knife, and is of great value in protecting the former from being accidentally wounded. On all grounds, therefore, whether in performing cataract extraction as a single operation, or in performing iridectomy as a preliminary step, the use of eserine to produce contraction of the pupil is important. My own practice is to apply to the conjunctiva, about half an hour before the operation, a single drop of a solution containing four grains of eserine sulphate to an ounce of distilled water. Some surgeons use a weaker solution, more frequently applied. Both methods, in all probability, answer equally well; and the only one about which I feel doubtful is the instillation of an eserine solution after the operation is completed. I should much fear that its entrance into the anterior chamber might be followed by injurious consequences.

The state of the pupil having been attended to, the next points for consideration are the size, position, and direction of the incision. I should lay down, as cardinal principles, that it should be proportionate to the diameter of the nucleus, so far as this can be ascertained; neither so small as to render the exit difficult, nor so large as to call upon the patient for unnecessary repair. It should be fully as large at its inner as at its outer aspect, not "tailed," so to speak, upon the outside of the eye, with a comparatively small opening into the

anterior chamber. It should lie in a plane sloping forwards from its extremities to its summit, because this position greatly facilitates the exit of the lens. The first step towards extrusion is to press upon the eyeball at or just below the lower margin of the cornea, and this pressure causes the lens to turn as if upon a horizontal axis, and to present with the upper part of the equator tilted somewhat forwards. If it meets with a wound of corresponding direction, it falls into it with readiness; while, if the wound be parallel to the plane of the iris, or still more if it at all trend backwards, the equator of the lens will come into contact with the inner surface of the cornea, in front of the wound, and will be arrested at a critical moment of the proceeding. The correct position is for the wound to lie in a plane which would pass through, or perhaps be a little in front of, the imaginary centre of the corneal curvature. A fourth, and not an unimportant condition, is that the wound of the deeper tunics should be covered by a conjunctival flap.

An incision which shall combine the foregoing characteristics can only be made by puncture and counter-puncture; and it follows that all lance knives must be discarded, save for the consideration that they have their uses in exceptional cases. If we take a common broad, flat, lance knife, and thrust it into the anterior chamber in front of the iris, the extremities of the incision, on account of the shape of the eyeball, will lie in a plane anterior to the centre, a condition the very opposite of that which is desirable. Weber endeavoured to overcome this difficulty by the use of a lance knife which was concave on its posterior surface, and Dr. Bell Taylor, by the use of a very narrow lance knife, with the edge of which he cut laterally after its introduction into the chamber, placing the whole length of his incision in the sclero-corneal junction. Neither method affords a conjunctival flap, and neither, according to my experience of them, affords a wound which opens readily for the exit of the lens. I would remark in passing, however, that Dr. Bell Taylor's incision appears to me to be the best which has yet been devised for the performance of iridectomy when there is a shallow anterior chamber.

The incision by puncture and counter-puncture requires a very narrow, thin, straight knife, with a fine point and one cutting edge. There are two patterns, that formerly employed by Linnhardt for flap extraction, which was adopted by Von Graefe and is commonly called by his name, and that of Dr. Bell Taylor. Von Graefe's knife has its back and edge parallel to each other, and its point is made by an equal sacrifice of both. As described by himself, the blade should be two millimetres broad, and three and a half centimetres long. Taylor's knife has a straight back, and is of the same length as Von Graefe's, but it may be likened to a very narrow Beer's, except that its point is wholly produced by the slope of the cutting edge. There is not much to choose between these forms, but, on the whole, I think that Taylor's encounters the less resistance of the two, and that its shape affords a better edge for the completion of the section.

The external points of puncture and counter-puncture were placed by Von Graefe on the same horizontal line, two millimetres below a tangent to the vertical meridian of the cornea, and on the tangents to the horizontal meridian. The margin of the true cornea, on its anterior surface, and especially at the upper part, is partially concealed by a covering of conjunctiva, through which the point of the blade would enter and emerge; while the centre of the incision would coincide with the apparent corneal margin, and thus be somewhat anterior to the true one. I do not think the position thus described can be widely departed from with advantage.

It is desirable, from an optical point of view, and also as a matter of appearance, that the iridectomy should be directly upwards, so as to be concealed by the upper lid; and it follows that the section should be bisected by the vertical meridian of the cornea. In order to secure this, whenever an anæsthetic is employed, the surgeon must be careful to note some landmark, some vein on the surface of the eye, or some spot on the iris, by which to be sure of the position of the vertical meridian. When under an anæsthetic, the eyes are often much rotated, and an incision which appears to be rightly placed when it is made, may be found, after recovery, to be very oblique in its direction.

The patient being placed upon his back on a couch, with his feet towards a sufficient window, the surgeon, standing behind his head, first carefully adjusts a speculum in such a manner as to keep the lids sufficiently apart with the minimum of pressure. He then takes the knife in his right hand for the right eye and in his left hand for the left, with the cutting edge upwards, and with the free hand seizes the conjunctiva, or if this be very fragile, the tendon of the inferior rectus, with fixation forceps, as near to the cornea as possible, and exactly on the vertical meridian. The fixation forceps should terminate in rather blunt extremities, with which, when needed, pressure may be made against the eyeball. The eye being thus secured, and slighted rotated downwards, the surgeon enters the knife at the spot indicated on the diagram,[1] endeavouring to turn its edge somewhat, but very slightly, forwards, and carries it downward through the anterior chamber, close in front of the iris, to a spot a little below and to the nasal side of the centre of the pupil. By this course, the perforation of the anterior chamber is a little lower than the external puncture, and the internal wound is made at least as large as the external one. The point of the knife is then raised until the back of the blade becomes horizontal, and is pushed on to the selected spot for the counter-puncture, great care being necessary not to be deceived as to the position of the blade by refraction through the aqueous humour or cornea. When the point of the knife emerges, the blade should have its back directed downwards and backwards, towards the centre of the corneal curvature, with the edge upwards and forwards in a corresponding degree; and, when the position is correct, the surgeon has only to complete the section. It is usually desirable to rotate the eye slightly outwards with the fixation forceps, so as to avoid wounding the eyelids, or the side of the nose; and then the section is completed, with Von Graefe's knife, by a gentle sawing movement, or with Taylor's, by simply pushing the blade straight onward. If, when the counter-puncture is made, the surgeon finds that the flat of the knife is parallel with the plane of the iris, so that the incision would not have the requisite forward direction, and that its centre would be placed too far back, it is necessary slightly to rotate the blade before enlarging the wound; but this proceeding is to be avoided whenever possible, because it tends to bruise the iris near the extremities of the incision, or in parts which will not be removed by the iridectomy. The section being completed very slowly, the aqueous humour leaks out and elevates the conjunctiva, so that this is not touched by the edge of the knife until after it has completely cut through the corneo-scleral junction. The edge is then directed backwards, and made to cut through the loosened conjunctiva two or three millimetres farther back, so as to leave a flap which may be turned down over the cornea by the blade.

The next step is the iridectomy, the object of which is merely to break the continuity of the sphincter and to avoid bruising or stretching of the fibres. The iris forceps should be introduced at the centre of the wound,

[1] Exhibited during the lecture.

*

carried to the edge of the pupil, and opened just widely enough to seize the narrowest possible fold. This should be gently drawn out of the eye, cut off with scissors up to its peripheral margin on each side of the forceps, and then cut, not torn, from its ciliary attachment. The remainder will generally at once return into the anterior chamber.

The division of the capsule of the lens is a proceeding which has much exercised the minds of inventors, and many ingenious instruments have been contrived for the purpose. I think there is nothing better than a simple steel point, set upon a flexible platinum stem, which can be bent with the fingers to suit the depth of the eyeball and the shape of the orbital margin. The operator should fix the eye at the original point whilst introducing the cystitome with its point directed laterally, but should make no pressure with the forceps, or should rather lift the eye towards him, until the point has passed beneath the lower margin of the pupil. It should then be turned down into contact with the lens capsule, and the least pressure with the fixation forceps will render the eye more tense, and will project the lens against the point. This should then be drawn gently to the equator, and then along the equator, in a direction parallel to the section, before it is withdrawn. As the capsule is divided, the lens may generally be seen to start forward, as if released, and a portion of the softened cortex will usually at once escape from the eye.

At this stage, it is often desirable to remove the speculum, and to raise the upper lid by a simple elevator, which, if the operator requires both his hands, may be committed to a careful assistant, who, at the same time, may draw the lower lid gently towards the lower orbital margin. The best elevator is, I think, that contrived by Dr. Noyes, of New York, which holds the lid securely, and takes up but little room. With or without fixation—which only becomes necessary when the eyeball is rolled upwards by the action of the superior rectus muscle, and which must then be managed with the greatest care, for fear of rupturing the hyaloid membrane and permitting the escape of vitreous—the operator makes gentle pressure immediately below the cornea, in a direction backwards, with the back of a tortoiseshell or caoutchouc spoon. Under this pressure, the nucleus should begin to turn, and its upper margin should present itself between the lips of the wound. The spoon pressure should then be continued in an upward direction, and the nucleus will gradually emerge, the pressure being relaxed as soon as its widest part has passed through the opening. The lids should then be suffered to close. In a few moments they should be reopened, the eye surface cleansed from cortex and coagula by gentle touches with a morsel of soft and carefully disinfected sponge, and the pupil and the wound examined. If the pupil be clear and black, and if the wound contain no iris, the operation is complete. If, on the other hand, the pupil be occupied by cortical substance, this must be extruded by gentle pressure, and by friction upon the cornea through the lower lid, or, if necessary, removed by the gentle introduction of a small spoon or scoop. Incarcerated iris may be replaced by a delicate whalebone spatula, or by gentle friction at the angles of the wound.

It has been assumed, in all the foregoing description, that the surgeon is dealing with a mature cataract, the whole of the cortex of which has lost its cohesion, and so slips easily out of the capsule, and has also lost its transparency, so that it is a conspicuous object within the eye, and cannot be overlooked. In dealing with immature cataract we have the reverse of these conditions, a greater or less thickness of the outer layers of the cortex being still adherent to the capsule, and being rendered practically invisible by transparency. More or less of this material will usually be left within the eye. After a short period of maceration in the aqueous humour, it swells up, becomes opaque and conspicuous, and sometimes appears to increase by cell proliferation. In some cases it is absorbed with little trouble, in others it excites iritis, it may be of a mild type, it may be of great severity; and the latter form, although, after modified linear extraction, it seldom leads either to suppuration of the globe or to sloughing of the cornea, yet sometimes extends to the choroid and to the ciliary region, produces wasting of the eye and loss of sight, and may even lead to sympathetic ophthalmia. The question of the propriety of extracting immature cataract will turn upon the probability of these risks being successfully avoided or overcome.

As a first step in this direction, it is essential to separate the iridectomy from the extraction by a time sufficiently long to allow of the perfectly sound healing of the cut edges of the iris. It hardly needs demonstration that the presence of swollen and possibly decomposing cortex within the eye will be much more likely to excite mischief, if it be in contact with a recently wounded iris, than with one which has completely recovered. As a rule, I think the interval between the two operations should not be less than six weeks.

The iridectomy itself should be performed with the smallest possible amount of disturbance to the eye. The incision, if there be a good anterior chamber, may be made with a very thin, rather narrow, and acute-angled lance knife, the aqueous humour should be suffered to drain away slowly, and a very small strip of iris should be drawn out and excised in the manner already described. If any portions remain in the angles of the wound, they must be carefully replaced by the spatula before the lids are closed. If the anterior chamber be rendered shallow by enlargement of the lens, the incision may be made in the manner already ascribed to Dr. Bell Taylor. For this purpose, the conjunctiva must be seized by fixation forceps close to the corneal margin, and immediately to the left of the left hand extremity of the intended wound. At this point, a very narrow bent lance-knife must be entered, and, when its point has been carried into the chamber as far as can be done without risk of wounding either lens or iris, the right hand edge must be made to cut its way around the margin of the chamber until a wound of sufficient length has been obtained, through which the iris may be drawn out and excised in the ordinary manner. Before the eye is closed, both the anterior chamber and the conjunctival sac should be freed from blood as completely as possible, and the bandage should be applied with moderate pressure. The patient should be kept in bed, under suitable regimen, cold wet compresses should be applied if there be any heat or pain, and every endeavour should be made to prevent or to subdue iritis. On the second or third day a drop of solution of atropine should be placed within the conjunctiva, and no risks should be run, and no use of the other eye permitted, until all blood has disappeared from the anterior chamber, all surface vascularity has passed away, and a free and moveable pupil is obtained. It is only when these conditions are fulfilled, that the case can be considered a hopeful one for farther treatment; and the iridectomy is not only valuable as facilitating the extraction, but also as a test of the healing power of the patient, and of the behaviour of the eye under injury. If the iridectomy were followed by iritis, it could scarcely ever be proper to proceed with the extraction prior to complete maturation of the cataract.

An occasional effect of the iridectomy, probably by the change which it produces in the intra-ocular tension, and hence in the state of the fluids within the eye, is to hasten the maturation; and, even in this way alone, it is sometimes of the greatest service to

the patient. I have seen a cataract, which was very incomplete at the time of the iridectomy, become absolutely mature within three weeks thereafter, and slip out of the eye, when the capsule was divided, without leaving a fragment of cortex behind.

When this fortunate result is not attained, but when the completeness of the recovery from the preliminary operation has been satisfactory, we may proceed to extraction as soon as this preliminary operation has, so to speak, been forgotten by the eye. In some cases, I have very gently divided the anterior capsule with a fine needle, so as to admit the aqueous humour to the cortex, and have then deferred extraction for one, two, or even three or more days, carefully watching the eye in the meanwhile, and ready to operate as soon as any symptom of irritation became apparent. In others I have divided the capsule immediately before making the corneo-scleral section, so as to have the lens better supported against the needle, and so as to be ready to apply pressure for extrusion as soon as the section was complete. This plan has been advocated, on general grounds, by Mr. Spencer Watson, and I am disposed to think that it offers some advantages. Unless one of these methods be pursued, the extraction does not differ from that already described, except in the fact that the iridectomy, having been done previously, does not need to be repeated. Another difference is that it is advisable, when the operation is finished, to close the eye in a temporary fashion for ten minutes or so, and then to endeavour to obtain the extrusion of some further portions of cortex, which, by that time, may have been detached from the capsule by the action of the aqueous humour. Of the after treatment, of the special risks which may arise, and of the methods of encountering them, I hope to say something in the next and concluding lecture.

REMARKS ON EXAMINATION OF THE NOSE.[1]

By E. CRESSWELL BABER, M.B. Lond.,
Surgeon to the Brighton and Sussex Throat and Ear Dispensary.

The nasal cavities form a region of considerable interest to the surgeon, whether we regard them as the seat of the organ of olfaction, as the uppermost part of the respiratory tract into which the Eustachian tubes open, or as accessory organs concerned in the production of the voice. They are thus intimately connected with the organs of smell, hearing and speech.

In the few remarks which, at the request of our secretary, I have undertaken to make before you this evening, I propose to give an account of the different methods of examining the nasal cavities, which I have found of more or less service, making reference in passing to several of the diseases to which these parts are liable, and illustrating my remarks when necessary by a brief allusion to cases.

The general term "nasal cavity" as used above, comprises two distinct parts, the *nasal cavities* properly speaking, which extend forwards on each side from the posterior margin of the septum nasi and the *naso-pharynx*, *upper pharynx* or *naso-pharyngeal cavity*, which forms, as you know, a single space situate behind the nasal cavities and above the soft palate, and communicating both with the interior of the nose and with the lower pharynx. Broadly speaking the interior of the nose may be examined by inspection and palpation. Inspection, technically termed rhinoscopy, may take place either from the front through the anterior nares or from the back behind the velum palati.

Anterior Rhinoscopy, or inspection through the anterior nasal apertures, may appear such a simple proceeding as scarcely to need any detailed mention; the amount of information gained, however, depends so much on the mode in which it is conducted, especially on the illumination employed, that a short description will not be out of place. In the absence of all appliances, by placing the patient opposite a strong light and raising the tip of the nose with the thumb, a view, more or less extensive, of the interior of the nares is obtained. This is usually, however, quite insufficient for a thorough examination of the nasal fossa, which necessitates the use of a speculum to straighten, and if necessary dilate, the yielding nasal orifice, and a means of throwing a powerful light into the same.

Nasal specula are of various kinds. The simplest, and one which may be extemporised at a moment's notice, is a bent hairpin, with which the ala of the nose can be drawn aside. Those in ordinary use are Fränkel's, consisting of two fenestrated blades, which are best bent at an angle to the handle and are separable by means of a screw, Duplay's and Voltolini's, which have concave polished blades, and Thudichum's. Fränkel's is the one which I usually employ. Löwenberg has recently described a speculum, devised for the special purpose of introducing the Eustachian catheter into the nose under guidance of the eye. It consists of a conical tube with a slit down one side. In small children, in whom the anterior nasal aperture is round, I have found a large aural speculum answer every purpose.

All these instruments require to be held in position by one hand, whilst the nose is being examined, otherwise, even if they keep in the nasal aperture without support, they fall downwards to such an extent, that no view of the interior can be obtained. In order to have both hands free in operations in the nose, I devised sometime since, and have frequently used with advantage, a very simple speculum, consisting of two wire hooks united by an elastic band, which passes round the patient's head.[2] This instrument not only holds itself in position, but keeps up the tip of the nose sufficiently to allow of examination of the interior. Zaufal's specula, which consist of long narrow tubes, for examining the deeper parts of the nose I shall allude to subsequently.

The second requirement is a good method of illumination. I fully agree with Voltolini, that by far the most satisfactory light for either anterior or posterior rhinoscopy is sunlight. Sunlight, *not* used by placing the patient opposite the sun and allowing the rays to fall directly on him, as by this means the observer's head is apt to obstruct, very uncomfortably, the rays of light, but sunlight employed by placing the patient with his back to the sun, and allowing its rays to fall into the room just above, or to the right side of his head, and reflecting them with a *plane* mirror into the nose or pharynx as the case may be. The mirror is attached to the forehead, and should be perforated in the centre, in order to allow of the observer's eye being in the direct axis of the light. Anyone who uses sunlight in this manner will be really astonished how, probably on account of its intensity and whiteness, its light reveals the condition of parts deep in the nose, with a clearness quite unattainable by the other methods of illumination in common use. Unfortunately, however, sunlight is not always to be had, and we are therefore often compelled to resort to artificial illumination—for I may say at once, that ordinary daylight, reflected by

[1] Paper read before the Brighton and Sussex Medico-Chirurgical Society, June 7th, 1883.

[2] See *British Medical Journal*, January 5th, 1881.

means of a concave mirror, is not sufficiently powerful for either anterior or posterior rhinoscopy. The best artificial light hitherto generally accessible is that of an Argand gas burner (whether a "Silber" or a "Sugg") with as large a flame as possible. This should be placed slightly behind and to the right side of the patient on a level with his ear, and the light thrown in by means of a concave glass reflector, such as is used for laryngoscopy. In the absence of a light of this descrption, a duplex paraffin or other steady lamp may be used. The oxy-hydrogen lime light and the magnesium light, I leave out of consideration on account of their expense or complicated character. I have said that hitherto the best artificial light generally accessible was an Argand lamp, but it is not unlikely that this statement may require modification before long, when the use of the electric light becomes more general. In fact, I hoped to have shown you this evening a new electric lamp for surgical purposes, which I have ordered over from Paris. It is a small incandescent lamp which can be attached to the forehead of the observer in the same manner as a reflector.[3]

Parts seen on Anterior Rhinoscopy.—In thus examining the nose, the first thing which usually attracts attention is the inferior turbinated bone, curving downwards in scroll-like fashion, and often nearly touching the floor of the nostril. It is important to remember that the mucous membrane covering the inferior turbinated bone is very loosely attached, and has intervening between it and the bone an erectile tissue, which often rapidly swells up, completely occluding the nostril, only to subside as rapidly in the course of a few hours. I have, at the present time, a choir-boy under my care, at the Throat and Ear Dispensary, in whom this phenomenon is well marked. He came to me on account of his singing voice being impaired, as I found, by nasal obstruction. When I see this boy one day his right nostril is obstructed, and the left patent; when I see him next time, on the other hand, his left nostril is obstructed and the right free. Continuing our examination through the anterior nares, by tilting the patient's head somewhat backward we see the middle turbinal, which appears more distant and usually smaller than the inferior. The mucous membrane covering it is more closely adherent and more shiny than that of the inferior. The superior turbinal is not, as far as I am aware, visible from the front. Turning the patient's face slightly towards the opposite side we see the septum, which, by bending the head forward until the chin almost touches the breast, we can trace downwards to the floor of the nostril. It is not usual to find the septum perfectly straight. Löwenberg, as the result of the examination of a large number of skulls, finds that it is so only once in every seven times. Deflections of the septum to one or the other side are very frequent, and often add considerably to the difficulty of examining the nasal cavities. Besides general bendings, it often presents eminences or protuberances projecting into the nasal cavities. One of the most common of the forms which they assume, is a conical projection at the anterior lower part of the septum, on a level with, and almost touching, the inferior turbinated bone.[4] The floor of the nostril is raised just at the entrance and then sinks down into a hollow. With regard to the depth to which all these structures can be seen (*i.e.* how far they can be traced backwards), this depends entirely upon the conformation of the individual nostril. When the septum is tolerably straight and the nostril fairly wide (without there being necessarily any abnormal dilatation such as occurs in ozœna), the eye can, with a good light, especially that of the sun, penetrate as far as the posterior nares and naso-pharynx, and that this undoubtedly is the case, is evinced by the fact that during deglutition the play of the palatal muscles in opening the Eustachian tube can be distinctly seen through the inferior meatus. The visibility of the movements of the palate in this manner, I have found to be practically a very good test of the permeability of the inferior meatus. Zaufal recommends his specula for examining the Eustachian orifice and naso-pharyngeal cavity from the front. I have not been encouraged to use them much, and for this reason—the *larger* ones are by no means easy to pass, unless the nostril is very wide, in which case, as just mentioned, the deeper parts can be well seen with the ordinary speculum, and with the *smaller* sizes the field of vision is so very limited that their value is exceedingly doubtful. Still, they may be of use in certain cases. A word as to the appearance of these parts in some of the commoner diseases. In chronic catarrh there is swelling and increased redness of the nasal mucous membrane, although it should be borne in mind that normally the mucous membrane of the nose is redder than that of the mouth. Further, as mentioned above, swelling of the erectile tissue over the inferior turbinated bone may take place, so that we should avoid the error of attributing all swelling to catarrh. In ozœna the nostril is usually dilated, often to a great extent, and the turbinated bones are atrophied, the nostrils being occupied by hard, fœtid crusts, which frequently lie on ulcerated surfaces. And here I may mention that before examining a nose, especially by anterior rhinoscopy, it is often necessary to remove the discharge by syringing, which is best done with *cold* salt and water, the cold causing the mucous membrane to contract. (It is sometimes less trouble, however, to wipe away any mucus by wool on a cotton-holder, as in the ear. Simple blowing with a handkerchief is sometimes sufficient.) Mucous polypi, which constitute one of the commonest affections of the nose, as is well known, very rarely originate on the septum. They usually arise from the superior or middle turbinal or from the intervals between the turbinated bones. They appear as pearly globular bodies of a lighter colour than the nasal mucous membrane. On account of the occurrence of irregularity of the bones, and in order to distinguish polypi from thickened mucous membrane covering these structures, it is generally necessary to sound them carefully with a bent probe under guidance of the eye. The softness and mobility of mucous polypi serve to render the diagnosis clear. A probe thus employed is often of much value in distinguishing the different intra-nasal affections.

Posterior Rhinoscopy, or examination of the nose from the back, is more difficult of execution than the preceding, as in this case it is not a question of looking straight into the nose, but of looking round the corner, as it were, formed by the velum palati. The appliances required are—(1) a powerful source of light; (2) a small mirror for introduction into the pharynx; and (3) usually a tongue depressor.

1. *Mode of Illumination.*—All that I have said on that head in considering anterior rhinoscopy holds good in the present instance, except that when an Argand burner is employed, the intensity of the light may be further increased by means of a bull's-eye condenser held close to the flame in a metal chimney. 2. Rhinoscopic mirrors resemble those used in examining the larynx, except that they are smaller, and that the mirror joins the shaft at an inclination rather more approaching to a right-angle. Those I am in the habit of employing vary in diameter from ½ inch

[3] *December 20th.*—I have now had this lamp (The "*Photophore Electrique Frontal*") in use for three months, and find it answer admirably for examination of the nose, throat or ear. It may be obtained of Trouvé, Rue Vivienne, Paris, or of Weiss and Son, Strand, London. I have given an account of it in (The *British Medical Journal* for November 10, 1883, to which I must refer for further particulars.

[4] For further details on this subject I must refer to Löwenberg's paper in the *Archives of Otology*, for March, 1883, or to an abstract of this paper in the *London Medical Record* for June.

upwards. The requirements of a good mirror are, that, besides the glass being perfect, it should not be thicker than necessary, and that the shaft should come off straight from the lower margin of the mirror, and not make an angle after leaving the mirror. These details are of importance, as in the confined space in which we have to work every millimetre is of consequence. It is sometimes an advantage to have the stem slightly bent, so as to be convex on its upper aspect. In order to introduce the mirror into the required position to gain a view of the posterior nares, it is necessary that the tongue lie very low on the floor of the mouth. In some cases the patient can accomplish this without any instrument, but usually it is necessary for the observer to depress the tongue, either with his index-finger or with an angular tongue-depressor. A tongue-depressor, to be useful for this purpose, should be thin, in order not to take up more room than necessary, and at the same time sufficiently broad to prevent the tongue from bulging up on either side. The object, of course, is to depress the back part of the tongue as much as possible without inducing retching; and how far it is safe to venture backwards can only be ascertained by experience. The *method of procedure* is as follows:—The patient being seated, in the sun and with his back towards that luminary in the case of sunlight being used, or with the lamp rather behind him and on his right side on a level with his ear if artificial light is employed, the observer seats himself directly opposite on a rather lower stool than the patient. The latter being directed to open his mouth widely—if possible, keep his tongue down and breathe quietly through his nose—the observer depresses the tongue gently but firmly with his index finger or with an instrument held in his left hand, and throws the light by means of the head mirror on the posterior wall of the pharynx. With the right hand he then introduces the previously warmed rhinoscopic mirror, until it almost, but not quite, reaches the posterior pharyngeal wall. If there be sufficient space between the soft palate and the posterior wall of the pharynx, a portion of the naso-pharyngeal cavity will then come into view. The first part seen is probably the posterior surface of the velum and uvula. By raising the mirror somewhat, and making it more nearly horizontal, a whitish vertical band is seen, the posterior septum of the nose, and this is a point which should always be looked for, as it serves as the most convenient landmark in this somewhat obscure territory. By raising the handle, so as to render the mirror more horizontal still, the upper broadening part of the septum becomes visible. Again, by turning the mirror sideways the two posterior nares come into view, in each of which, always the two lower, and generally the upper, turbinated bones are seen. The inferior turbinated bone is grey in colour, and is often only partly visible, the lower portion being hidden by the velum. Turning the mirror still more obliquely to one side, we see the orifice of the Eustachian tube surrounded by its cartilaginous lip. Behind it appears Rosenmüller's fossa, a depression of some practical importance, as being the spot where the point of the Eustachian catheter often becomes engaged instead of in the Eustachian orifice. By placing the mirror nearly horizontally, the roof of the naso-pharynx can be seen occupied by irregular elevations formed by the pharyngeal tonsil; and by making it still more nearly horizontal, the posterior wall of the naso-pharynx comes into view very much foreshortened. In commencing an examination, it is perhaps well to use a small mirror; but it must be borne in mind that the larger the mirror, not only the greater the extent of surface visible without changing its position, but also the better the illumination of the naso-pharynx, for the mirror of course serves the double purpose of transmitting the light into the naso-pharynx, and of reflecting the image into the observer's eye. Also it is obvious that the higher and more vertically the mirror can be placed, the more direct (*i.e.*, less foreshortened) will the view of the posterior nares be.

Now, our great enemy in carrying out posterior rhinoscopy is the soft palate, which, if in the least irritated, and often without any irritation whatever, directly the patient opens his mouth, rises upwards, cutting off all access to the naso-pharynx from below. Various means may be adopted for causing it to descend, such as making the patient sniff up through his nose, making him pronounce the French word "on," causing him to make a snoring movement, etc., any of which are sometimes effectual, and are often of much use in cases in which there was a fair space *before* the palate contracted. But unfortunately, there are instances in which even when the velum is relaxed, there is scarcely any interval between it and the pharyngeal wall. If, in a case of this description, sufficient view cannot be obtained by means of the *smallest* sized mirror, it is necessary to employ some means of drawing forward the soft palate. Many have been the instruments devised for this purpose, hooks of various kinds and shapes, from the original one of Czermak, to the one recently recommended by Voltolini, the passage of a ribbon by means of a Belloc's sound round the soft palate, various uvula snares and forceps, etc,, etc. These all, as far as I know, have the drawback that in the great majority of cases, any attempt to draw forward the velum with them, produces so much irritation, accompanied by retching, that the instrument has to be precipitately withdrawn. Voltolini has in his work on Rhinoscopy, so strongly recommended the use of his hook in a large proportion of the cases that are met with in daily practice, that I have given it a trial in a considerable number of patients, as the result of which, I am sorry to say, that my experience hitherto does not accord with that of the inventor[5]. I have found, in fact, that usually the hook produces too much irritation to allow of its being used, but where I have really found it of value, is in cases such as those we are just considering, in which, as the Germans say, there is *Rachenenge*, *i.e.*, a very small interval behind the soft palate. By accustoming the patients to the use of the hook, in cases of this description, a good view of the naso-pharynx can be procured, which would otherwise be quite unattainable. My own experience is that in the great majority of cases, with patience and the use of a small mirror, a view of the posterior nares, sufficient for practical purposes, may be obtained without any hook. As in applying the hook, both hands are required, one for the hook, and the other for the mirror, Voltolini has recommended an automatic tongue-depressor. I have not had much success with this, as it is apt to slip off, besides not depressing the tongue sufficiently. I have found it much more simple and convenient to let the patient hold down his own tongue with an ordinary depressor.

Palpation of the *anterior nares* is of course simple enough. The well-oiled little finger being insinuated into the anterior nares, serves to diagnose swellings on the septum, etc. But it is palpation of the *posterior nares* to which I wish particularly to draw your attention. This method of diagnosis is one which I think is not sufficiently employed. It has the great advantage over posterior rhinoscopy, that it can be carried out without either any previous training on the part of the patient, or special skill on that of the surgeon. It is most conveniently performed as

[5] I may remark that Voltolini considers the large size of his hook very important, as enabling it to obtain a firm grasp over the palatal muscles.

follows :—The patient being seated, the surgeon stands to one side of him, and steadying his head by means of one hand on the vertex, passes the forefinger of the opposite hand (preferably the left, on account of its smaller size) rapidly to the posterior wall of the pharynx, and up behind the soft palate, until the posterior septum is felt as a hard thin ridge. On the two sides, the inferior turbinals give the impression of soft cushions, which one is very apt to mistake for polypi, especially if they are at all swollen. This error may however easily be avoided by a comparison of the sensation experienced on the two sides. The situation of the Eustachian orifices can also be felt, although I am not aware that any diagnostic fact of importance can thus be ascertained. A most important part to examine, is the roof and posterior wall of the naso-pharynx. Its importance rests on the fact that it is in these two situations that *Adenoid Vegetations* have their seat. Normally these have, it is true, a somewhat uneven surface, but when adenoid vegetations are present, they present more or less pedunculated growths of all sizes and shapes, which, in well-marked cases, completely fill the naso-pharynx, giving to the finger the sensation of a bunch of worms. This disease, which is a very common one in childhood, was first described by Meyer, of Copenhagen. I have given a short account of it in the *British Medical Journal* of Aug. 5, 1882. Palpation of the naso-pharynx must be rapidly executed, as it is disagreeable to the patient, and liable to produce retching. In children and refractory patients, it is well to guard the first phalanx of one's forefinger with an india-rubber ring; and the finger may, as I found, with advantage, be lubricated with a mixture of glycerine and water. After palpation has been repeatedly practised, the sensitiveness of the parts becomes to a certain extent blunted.

It is hardly necessary for me to say, that before proceeding to the physical examination of the nose, in the manner I have described, the history of the case should be made out, and the subjective symptoms, both general and local, from which the patient is suffering, carefully ascertained. It is also well to test the perviousness of the nostrils, by making the patient blow through them alternately,

The practical conclusion which may be drawn from these remarks, is, I think, the following, viz. :—Anterior rhinoscopy and palpation of the naso-pharynx are valuable means for the examination of the nose, which are at every surgeon's command, and the two together, will often suffice to make a satisfactory diagnosis. A *complete* examination of this organ, however, necessitates the employment of posterior rhinoscopy, which, generally speaking, needs only a little care and patience on the part of the surgeon for its successful performance.

(The paper was illustrated by several diagrams and by numerous instruments.)

Agaric in Night-sweating in Phthisis.—In the *Wiener Med. Wach.* (1883, No. 38), Dr. Otto Seifert, after repeated trials, speaks highly of the efficacy of agaric in the night-sweats of phthisis, as recommended by Dr. Young in the *Glasgow Med. Journal*, 1882, p. 176. He employs the active principle of *agaricus albus* as prepared by Merck of Darmstadt, in pills of a minimum dose of five milligrammes, which may, if necessary, be increased to a maximum of two centigrammes. Comparative trials convinced him that the *agaricin* is most efficacious when administered as soon as the sweating commenced, instead of some hours before. The remedy may also be given as a subcutaneous injection with the same effects, but the burning pain it causes induces patients to refuse to submit to its repetition.

A CASE OF COMPOUND FRACTURE OF A FINGER WITH SUBSEQUENT CARIES OF BONE TREATED SUCCESSFULLY ON CONSERVATIVE PRINCIPLES.

By WILLIAM BAIN, L.R.C.P., L.R.C.S.

H. T., aged two years, received a compound fracture of the first phalanx of the right middle finger, with severe laceration of the tissues, on the 16th February, 1883. The accident occurred through the boy slipping his hand between the cogged wheels of a wringing machine while they were in motion. The first phalanx of the middle finger of the right hand was chiefly affected. Posteriorly a ragged wound, nearly three-quarters of an inch in length, extended from about the centre of the web between the middle and ring fingers in a vertical direction, to a point a little above the knuckles. Anteriorly a lacerated wound extended from the palmar groove in front of the metacarpo-phalangeal joint in a slightly oblique direction along the third metacarpal bone for half an inch. The tissues over the palmar aspect of the first phalanx were completely removed down to the bone, with the exception of the tendon of the flexor profundus digitorum, which was drawn to the left side of the protruding bone; not a vestige even of the periosteum was left. A very small portion (probably about an eighth of an inch) of the distal end of the bone was carried off, while the artificial end thus produced projected almost directly forwards for nearly a quarter of an inch from its usual position. The bone was quite bare from the terminal end to the palmar groove already mentioned. Hæmorrhage was very trivial. Two silk stitches were employed to bring together the edges of the posterior wound. The raw surfaces of the anterior wound were brought into close apposition by two silk sutures. I now directed my attention to the bone. I pushed it into its proper place and drew the tendon over it, so as to aid in retaining it in its normal situation. I then attempted, by means of two silver sutures, to draw the mutilated tissues at the sides of the finger into as close proximity as possible over the bone. Notwithstanding a good deal of traction, a gap of an eighth part of an inch intervened between the edges of this wound. A well padded splint, extending from the tip of the finger to the wrist, was applied along the dorsal aspect of the hand, and kept in position by strapping. Carbolic acid dressings were employed throughout. The spray was not used.

For a few days everything went on satisfactorily. The anterior and posterior wounds did well, but in less than a week's time the flexor tendon sloughed away, and a few days after the silver stitches lost their hold, thus permitting the bone to project, as at first. I put small pledgets of lint over the bone, and strapped it down with adhesive plaster. The pressure thus applied, produced irritability of the wound and consequently had to be discontinued. I then put on an angular splint. I thought that, if the finger was kept in a bent position, the bone would be less likely to project, but I was again destined to disappointment. The bone projected do what I would, unless pressure was directly applied to it. I next devised a very simple apparatus—a tack, the head of which was held between two layers of isinglass plaster, the pointed extremity being in contact with the bone, and the length of the tack precluding the possibility of pressure by the plaster upon the edges of the wound. This caused the little patient some pain, and on removing the dressings I found blood had been extravasated from the bone. A piece of cork was next laid along the bone, which was secured by strapping. This acted very effectually for a time, but

three days after this procedure had been adopted the bone died. The odour was so very offensive that all hope of saving the finger was now reluctantly abandoned. On the 7th of March the child was put under the influence of chloroform in order to have the finger taken off. Like "a drowning man catching at a straw" I again explored the doomed digit, and having removed all I could of the dead bone, which included the first phalanx as far back as the palmar groove already referred to, I dressed the wound, readjusting the straight splint as before, determined to persevere to the last in the treatment I originally recommended. I may mention that the child's health now began to suffer. He became fretful, restless at nights, appetite impaired, tongue furred, and there appeared on different parts of the body a few papular spots, some of which developed into pustules. These symptoms may have been due to dentition. In a few days the wound lost its offensive odour, and looked healthier. In a week's time a profuse crop of unhealthy looking granulations sprang up, to which I daily applied nitrate of silver, which eventually caused their disappearance. The finger was very much thickened, especially that part from which the dead bone was removed. About the beginning of April the wound was nearly healed; in fact, I told the mother that it would be unnecessary for me to call again; but some days after a small abscess in the site of the wound burst, and a series of these prevented it from being thoroughly healed until the 21st of May.

I may state that two medical friends saw the case several times. One of them was summoned along with me on the day of occurrence, and advised immediate amputation of the mutilated finger.

June 12th.—The finger looks well. It is shorter than natural. The part from where the carious bone was removed is still enlarged. He can extend the finger at will, but flexion is impaired.

December 18th.—The finger has improved very much in appearance. It is not quite as long as the forefinger. The enlargement is gradually disappearing. The first phalanx feels firm, as if there were some spiculæ of bone in it.

Remarks.—I think the case is a fair example of the triumphs achieved by conservative surgery. If I were to have a similar case again, I should at once excise a portion of the projecting bone, and instead of inserting wire sutures I should use catgut, treating the wounds antiseptically. I think the silver stitches caused irritation, especially as so much traction was absolutely necessary if they were to be of any value. If the bone could have been retained in its proper position without pressure on the wound or injury to the bone, I feel sure the case would have done well. It was suggested to me to cut the second and third dorsal interossei muscles (which I considered the cause of the bone projecting), but I did not feel myself justified in attempting a proceeding of doubtful utility and requiring such nicety of execution. It might be asked, is it absolutely justifiable in order to save a finger to expose a child for three months to the risk of septicæmia? I think so. The boy, when he attains the age of manhood, will most probably earn his livelihood by the use of the pen, and the finger will be of great advantage to him in wielding that instrument. Besides, should septic poisoning supervene, or any other untoward symptom, amputation could at once be resorted to and thus avert any dangerous tendencies.

The Glasgow Convalescent Home.—The annual meeting of the subscribers was held on the 15th instant. The report for the year showed that 1,450 patients had been treated, at a cost of £2,077. The average stay per patient had been 18¼ days, and the average cost 1s. 6¼d. a day.

REPORTS OF HOSPITAL PRACTICE IN MEDICINE AND SURGERY.

ST. MARY'S HOSPITAL.

CASE OF ANEURYSM OF RIGHT ULNAR ARTERY.

(Under the care of Mr. EDMUND OWEN.)

(For the report of this case we are indebted to Mr. Herbert Tanner.)

James W., aged 38 years, a strong, healthy-looking labourer, was admitted to the Thistlethwayte Ward on November 12th, 1883. He had suffered but little from disease of any kind, having had only rheumatic fever, when he was 18 years old; but he acknowledged having been a great drinker up to within the last year or two. No evidence of syphilitic taint could be obtained.

He was accustomed to work chiefly with a spade, and was thus engaged five weeks before admission, when he first had symptoms that something was wrong with the upper part of his right forearm; he noticed a small tumour, about the size of a nut, which gradually increased till at the end of a month it was as large as a walnut, the pain in the part proportionally increasing and extending down the forearm to the hand chiefly to the radial side. A week before admission he had to use a heavy hammer in his work, and during this time the swelling increased rapidly. During the day when he first experienced pain, he had not noticed any snap or "giving way" in the limb whilst at work.

On admission, he was found to have an enlargement at the upper part of right forearm, about level with the neck of radius, but chiefly to the inner side of the median line; this swelling was found to pulsate distinctly on applying the fingers, and they were sensibly and visibly separated laterally at each pulsation; a very distinct bruit was to be heard by means of the stethoscope. The tumour was situate at the anterior aspect of the limb; the circumference of the forearm just at this point measured 12½ inches, whilst that of the left limb at the same level was 11⅜ths inches, but there was greater muscular development on the right than on the left side. The swelling could be felt to be circumscribed, of about the shape and size of an egg. Pressure applied to the brachial artery completely arrested the pulsation of the tumour, which immediately re-apppeared on removing the pressure; the pulsation was also arrested by strong flexion of the elbow joint, but this gave great discomfort. The pain he felt chiefly on the anterior aspect of the forearm and wrist, and also had a numbed sensation in the thumb and fingers, corresponding exactly to the anatomical distribution of the median nerve, viz.:—at the palmar aspect of the thumb, at both sides of the index and middle fingers, and at the radial side of the ring finger, as well as at the dorsal aspect of the lower half of the three digits mentioned.

There was pulsation in the radial arteries of both limbs, but none could be felt in the ulnar of the right side. The superficial veins of the limb were dilated, owing to the pressure upon them above, and a hyperæmic blush covered the site of the tumour; but this was due to the fact that the patient and his friends had diagnosed the abnormal condition as "rheumatic," and had been treating the part by application of mustard poultices. The anterior branch of the superficial temporal artery was compressible and not tortuous; the urine quite normal. The pulse was 48, soft and compressible, and the right hand was sensibly hotter than the left.

Operation:—On November 14th, ether having been administered, Mr. Owen ligatured the brachial artery

in the middle of its course; a catgut ligature was applied, and the pulsation of the aneurysm immediately ceased. The wound was syringed out with a weak solution of iodine, a small drainage tube put in, and the edges were brought together by silver sutures. A sponge, squeezed dry from the iodine solution was laid over the wound, and over this a pad of salicylic wool, and the whole limb enveloped in a thick covering of wool.

The patient did not sleep during the night following the operation, the limb being in much pain; the hand felt warm the next morning, the pulse was 120, temperature subnormal. The wound was redressed every alternate day, was very healthy—iodine solution and salicylic wool being used throughout.

On the 20th November—six days after the operation—the wound was healed, except where the drainage tube lay; two days later all the cotton wool was removed, and the aneurysm was found to be completely solid. Circumference of limb 11½ inches, where previously it measured 12¼. The limb was encased in the semiflexed position in plaster of Paris to insure absolute rest.

On the 27th (13 days after operation), the plaster case was removed, the wound being completely healed, and the tumour solid and hard. Radial pulse distinct, but none to be detected in ulnar artery. Patient, being very anxious to go home, was discharged on December 4th, promising to keep the limb in a sling, and not to use it for a week or two.

The temperature was subnormal the whole time under treatment, except on the third day after operation, when it reached 99°.

Remarks (by Mr. Tanner).—This case is of much interest, in that it is so typical of the aneurysmal condition—typical in its mode of origin, and in its successful removal by ligature of the vessel on its proximal side on Hunter's principle. Judging by the history of the patient's past life, and of the commencement of the aneurysm, there can be little doubt that the condition arose from degeneration of the arterial wall, brought about by that potent agent in degeneration—physical and moral—alcohol. The aneurysm was felt to be distinctly circumscribed, and the history of its commencement points to the fact that there was not rupture of the arterial wall as a whole. The symptoms of aneurysm were all present to a remarkable degree of distinctness, and its pressure-effects on the contiguous nerve, the median, were highly interesting. The irritation of the median nerve was most distinct—the patient pointing out the exact distribution of the sensory branches of the nerve by indicating where he felt pain or abnormal sensation as correctly as if he were an anatomist. The effects of the operation were completely satisfactory. The day after the operation collateral circulation was well established.

MANCHESTER HOSPITAL FOR SICK CHILDREN.

CASE OF GLIOMA OF THE PONS, PARALYSIS OF RIGHT SIXTH AND SEVENTH NERVES, AND HEMIPLEGIA.

(Under the care of Dr. HENRY ASHBY.)

JOHN M., æt. 9 years, was admitted to the General Hospital for Sick Children, Feb. 19, 1883. His mother stated he was quite well till a month before Christmas, 1882; it was then noticed that he held his head flexed towards the left shoulder, and had a peculiar gait, throwing his legs forward. About Christmas time, it was noted that he turned his right eye inwards, that his face was drawn, and that he vomited at times when he got up in the morning. The vomiting sometimes continued all day, and at times he complained of pain at the back of his head. He had never had any convulsions, and there was no history of an injury of any kind.

Present state.—He is a well nourished boy with a somewhat heavy look. He has almost complete right facial paralysis; on attempting to close his eyes, the right only slightly closes, being turned upwards and inwards; the angle of the mouth is drawn to the left, the right side of face being quite motionless. There is paralysis of the right external rectus, the eye-ball moving up and down and in, but not outwards. The pupils are dilated, but act to light. The grasp of the left arm is weak, but he can use it, the left leg is also feeble, though he can walk; knee-jerk present, but most marked on the left side. No loss of sensation on the face, but there seems to be some loss in the left hand, as he either doesn't feel a prick, or refers it to the wrong finger. Sight fairly acute; both optic discs are swollen, edges blurred, veins very full; no hæmorrhages. P. 116. T. 99°.

Feb. 27.—Vomiting has been very troublesome since admission; last day or two has been fed per rectum; abdomen retracted; is very drowsy.

March 13.—Since last note has had a scarlatinal rash and slight elevation of temperature; vomiting better.

March 26.—Vomiting very troublesome; fed per rectum; is very drowsy.

April 4.—Vomiting better. Talks and answers questions; evident loss of sensation in left arm; can sit up, but cannot stand by himself.

April 8.—Vomiting continuously, is drowsy and can hardly be roused; the left eye-lid droops, both pupils are dilated and sluggish; left upper extremity quite powerless, sensation impaired. Both lower extremities can be moved voluntarily, but are weak; knee-jerk and ankle-clonus present in right, both absent in left.

April 10.—Death.

P.M.—Body thin, but not wasted.

On removing the brain and placing it base upwards, it is apparent that the pons is larger than normal, especially on the right side, where its surface is irregular from the presence of small nodular projections. The sixth and seventh nerves of the right side have been evidently flattened and stretched, as they pass round the lower border of the pons. The vagus is also pushed away from the median line, the fifth not much interfered with. On exposing the fourth ventricle, by placing brain base downwards and dividing the median lobe of the cerebellum, the floor is seen to be occupied by an elastic swelling 1⅓ inch in diameter, and separating the restiform bodies; the swelling contained mucoid fluid. The cerebum is normal, the lateral ventricles distended. The cerebellum healthy, except some softening where it is in contact with the swelling in fourth ventricle.

On section through pons, it is seen that its right inferior part is occupied by a firm grey infiltration, which has expanded its substance irregularly and encroached on surrounding parts; the infiltration involves the whole thickness of the pons anteriorly and posteriorly, and encroaches on left side, and it has undergone mucoid degeneration, forming the fluctuating swelling present in fourth ventricle. The limits of the tumour cannot be well defined, as it shades away imperceptibly into surrounding parts. On microscopic examination, the tumour proved to be a glioma.

Remarks—From the first but little difficulty existed in localizing the tumour. Paralysis of the sixth and seventh of the right side, with a left hemi-paresis, pointed plainly to a tumour involving the lower border of the right side of the pons. This diagnosis was still further strengthened as the paralysis of the left arm and leg increased, and the vomiting, pointing to interference with the vagus, became continuous. Gliomata are comparatively rare during childhood, tubercular masses being infinitely more common.

Medical Times and Gazette.

SATURDAY, JANUARY 26, 1884.

Mr. Brudenell Carter's second Lettsomian Lecture (which will be found in another column), was delivered before the Medical Society on Monday evening last. The lecturer first alluded to the question of "maturity," or "immaturity" of cataracts. The word "maturity" he said, "was understood to signify that the degenerative changes had spread to the whole thickness of the lens," and he pointed out how this maturity might generally be guessed at. The advantages of waiting for maturity were balanced against its manifest disadvantages; maturity sometimes requiring years, during which, of course, the unfortunate patient was practically without eyes—where the means of livelihood depended on good eyes, this waiting became disastrous. The conditions which justified early operations were next dwelt upon, and the latter part of the lecture was devoted to a lucid description of the procedures most usually and successfully practised in this and other countries. The final lecture will be delivered on February 4th, and will embrace the questions of after treatment, the special risks of the operation, and the most approved methods of encountering them.

At the meeting of the Medical Society on Monday evening, the 28th inst., the president, Sir Joseph Fayrer, will read a paper on snake poison, and its treatment. The paper will be founded on a case which was under the author's care. As the author of a magnificent work on the Thanatophidia of India, Sir Joseph is well qualified to speak on the subject of snake poison: he will, doubtless, have a large and appreciative audience. On February 11th, Mr. Bryant will introduce the subject of irreducible hernia, and Mr. Jonathan Hutchinson will contribute a paper on "Lupous Disease of the Skin;" Feb. 18th and 25th will be devoted to a discussion on the cold bath treatment of enteric fever, in which Drs. Coupland, Bristowe Barlow, F. Taylor, Gilbart Smith, Samuel West, and Myers, will take part; and on Monday, March 3rd, Surgeon-General Hunter will read his deferred paper on "The recent Epidemic of Cholera in Egypt."

At the Royal Medical and Chirurgical Society, on Tuesday last, Dr. Roy gave an address on the "Mechanism of the Blood Pressure." Owing to the length of time which it occupied, to its fragmentary character, and to the fact of its even then being incomplete, the communication fell somewhat flat, and there was no discussion on it. It were much to be wished, on many grounds, that such addresses should be carefully prepared and written out; for then much needless repetition would be avoided, and the practical points would be more clearly stated. Dr. Roy had evidently taken great pains with his subject, and doubtless had many new and important facts to communicate, which, owing to diffuseness and want of co-ordination, were quite lost on the bulk of his hearers.

The President, at whose invitation Dr. Roy had made this communication to the Society, expressed his satisfaction with it, and the hope that others of a similar kind might follow. He thought there were subjects of great physiological and pathological importance which ought to come before them, rather than before the Royal Society to which such papers were usually offered. We can only hope, if such papers do come before the Medical and Chirurgical Society, that they will be subjected to the same rules and restrictions as regards length and reading, which apply to other communications. The object of the Society is to discuss, and not merely to listen to addresses.

Mr. Victor Horsley, at the same meeting, briefly described, as a preliminary communication, the specimens exhibited by him illustrating the existence of nerve fibres (special) and end bulbs, with also Pacinian bodies in the epineural sheath of nerve trunks. The specimens consisted of horizontal sections of nerve trunks treated with osmic acid and alcohol. They showed delicate nerve fibres accompanying the blood vessels and possibly vaso-motor nerves, while in addition there were separate fibres running parallel with the primitive bundles, and terminating either in a simple end bulb or a Pacinian body. These nerve fibres, possibly of sensory function, were shown to arise from either the primitive bundles or from branches of the same. All but one of the sections shown were from the human subject, in cases where emaciation had removed the fat with which the epineurium is thickly packed.

The Council of the Royal Medical and Chirurgical Society are anxious to find a successor to Mr. Wheatley, their late resident librarian, with as little delay as possible. They can hardly expect to get such efficient services as they have been accustomed to, but the inducements detailed in our advertisement columns are such that they ought to find no difficulty in filling the post.

The discussion on Surgeon-General Hunter's paper on the Origin of the Cholera Epidemic in Egypt, read before the Epidemiological Society, will take place on Wednesday February 13th, at 8 p.m., at 11, Chandos-street, Cavendish-square. It is expected that many members and visitors, interested in the subject, will take part in the discussion, and it is requested, with a view to the convenience of the meeting, that those gentlemen intending to do so, should communicate with Mr. Shirley Murphy, the hon. secretary, not later than Monday, February 11th. It is proposed to limit each speaker to ten minutes, and the names will be noted in the order of the receipt of their applications. The discussion will be opened by Sir William Smart, K.C.B., followed by Surgeon-General Balfour.

At the Annual General Meeting of the Odontological Society, which took place on the 14th instant, the following members were elected to serve as office-bearers for the year 1884:—*President*, Jas. Smith Turner, M.R.C.S. and L.D.S., Eng.; *Vice-Presidents*,

Messrs. Henry Moon, T. Charters White, and Geo. Gregson (Resident), and Wm. Doherty, of Dublin, J. T. Browne-Mason, of Exeter, and Richard White, of Norwich (Non-resident); *Treasurer*, Jas. Parkinson; *Librarian*, Felix Weiss; *Curator*, S. J. Hutchinson; *Editor of Transactions*, Henry Sewill; *Hon. Secs.*, Messrs. J. H. Mummery (Council), David Hepburn (Society), and R. H. Woodhouse (Foreign Correspondence); *Council*, Messrs. G. A. Ibbetson, Ashley Gibbings, Thos. A. Rogers, Chas. S. Tomes, F. Canton, Alex. Cartwright, W. St. George Elliott, Augustus Winterbottom, and Storer Bennett (Resident); and R. Rogers (Cheltenham), W. Hele (Carlisle), A. Wilson (Edinburgh), J. Fenn Cole (Ipswich), Geo. McAdam (Hereford), and W. E. Harding (Shrewsbury), Non-resident. Mr. J. Bland Sutton, Lecturer on Comparative Anatomy at the Middlesex Hospital Medical College, read a paper on "Comparative Dental Pathology," illustrated by means of a number of interesting specimens and drawings, in which he had attempted to collect and classify all that is at present known of the diseases of the teeth in animals. The retiring President, Joseph Walker, M.D., afterwards delivered a short valedictory address, in which he expressed a strong opinion that some changes were necessary to make the society more attractive to the junior members of the profession, and to enable it to maintain its position against the rivalry of younger institutions.

M. Paul Bert's method of administering chloroform was discussed at the meeting of the Académie des Sciences on Monday last. M. Gosselin characterized M. Bert's apparatus as unwieldy, inconvenient, and unsuited for ordinary practice. It was true that in the ordinary simple method of administering the anæsthetic on a handkerchief, one could not accurately say how much air was mixed with the anæsthetic vapour, but one proceeded with caution, intermitting the administration from time to time, watching the patient carefully, and regulating the anæsthetic according to the symptoms observed. The objection to M. Bert's method was that one was obliged to administer the same proportion of chloroform from the beginning to the end of the operation. That was a defect which might sooner or later lead to an accident. But M. Bert's experiments would have served at least to prove that the amount of chloroform required to produce anæsthesia is comparatively small, not exceeding eight grammes (two drachms), and that large doses are as unnecessary as they are dangerous. M. Bert desired that the discussion on his gasometer should be delayed until he could make it more portable and manageable. Theoretically one could hardly hesitate to choose between the two methods. M. Gosselin rejoined that the adoption of the gasometer meant the substitution of a blind mechanism for the series of intelligent and voluntary acts, by which the administration should be conducted, and which should ensure its success.

Mr. R. Clement Lucas has been elected a corresponding member of the Société de Chirurgie of Paris.

The metropolis keeps remarkably healthy. Last week the deaths were 326 below the ten years' average, nearly half of that number being accounted for by the comparatively low mortality from respiratory diseases. Of the zymotic diseases, whooping cough was the most fatal. It caused 69 deaths, which was still eight below the average. The deaths from enteric fever on the other hand, which numbered 24, were eight above the average. The deaths from diphtheria, sixteen in number, also exceeded the average by six, but, in this particular instance, we fear the returns are not altogether reliable. Though many more cases are probably admitted to be diphtheria now than at any previous time during the ten years from which the average is taken, there are, no doubt, still an appreciable number of deaths from the disease registered under other names. The disease continues very fatal in Berlin, where in the last week of last year 69 deaths from it were recorded.

On Thursday, January 17th, the Right Hon. George Otto Trevelyan, M.P., received at the Chief Secretary's Office, Dublin Castle, an influential and representative deputation from the Dublin Sanitary Association, the Royal College of Surgeons in Ireland, the Irish Medical Association, and the Dublin Branch of the British Medical Association, on the subject of the Notification of Infectious Diseases. The different speakers freely admitted the necessity which existed for some such means of checking the spread of epidemic diseases, and urged upon the Chief Secretary, as the representative of the Irish Executive, the importance of introducing to Parliament, a bill on the lines of that prepared and brought in by Mr. Charles Meldon, M.P., in the session of 1882. That measure laid the onus of compulsorily notifying the occurrence of infectious disease upon the person in charge of the sick individual, or the occupier or owner of the infected house, but left it optional to the medical attendant to notify, if he should think fit himself to do so. In this latter case the responsibility of notifying would be transferred from the occupier to the physician. Mr. Trevelyan promised to give the matter his careful consideration.

We understand that Mr. Richard G. Butcher, lecturer on operative and practical surgery in Sir Patrick Dun's Hospital, Dublin, and examiner in surgery in the University of Dublin, is in a very delicate state of health.

It may be in the recollection of our readers, that the Union Officers' Superannuation Bill (Ireland) brought in last session by Mr. Herbert Gladstone, M.P., was lost in the committee stage in the House of Commons, at the very close of the session. On Wednesday, the 23rd instant, a deputation from the King and Queen's College of Physicians, the Royal College of Surgeons in Ireland, the Irish Medical Association, and the Dublin Branch of the British Medical Association, waited upon the Chief Secretary to the Lord Lieutenant at Dublin Castle, to urge upon him the importance of re-introducing the Bill of last session, as a Government measure, early in the coming session. Replying to the deputation, Mr. Trevelyan said he would confer with Mr. Herbert Gladstone on the

subject, and that if he saw his way to again bring forward the measure, he (the Chief Secretary) thought the Government would actively co-operate in the endeavour to carry it through Parliament.

On Tuesday, January 8th, a deputation from the Pharmaceutical Society of Ireland waited on the Chief Secretary to the Lord Lieutenant, at Dublin Castle, to draw attention to certain defects in the "Pharmacy (Ireland) Act, 1875," and to suggest various amendments. The deputation consisted of Mr. James E. Brunker, M.A., Univ. Dubl., the President; Mr. Harry N. Draper, F.C.S., the Vice-President; and Messrs. Allen, Collins, Grindley, Hodgson, Montgomery and Simpson; Mr. Hugh James Fennell, Registrar, accompanied the deputation. It appears that throughout the greater part of Ireland the "Sale of Poisons" Act is at present a dead letter, poisonous substances being sold in the small country towns and villages by hucksters, stationers, ironmongers, grocers and others. The majority of the Council of the Pharmaceutical Society thought that it would be in the interest of the public that in future all persons should be licensed to sell poisons only on passing a moderate examination. It was proposed to call such persons "Registered Druggists." The Chief Secretary said he would do all in his power to meet the wishes of the deputation, the members of which then withdrew.

At last Saturday's meeting of the Metropolitan Asylums Board the proposal to build a convalescent hospital for fever and small-pox at Winchmore Hill was opposed with a perseverance which almost amounted to obstruction. Four divisions, all practically involving the same point, had to be encountered before the scheme was finally passed by a majority of 27 to 17. The Local Government Board has still to give its approval, but it is hardly to be expected that that authority will place difficulties in the way of a proposal which, if it throws an additional burden on the ratepayers with one hand, will probably take off ten times that burden with the other. Have the managers who oppose the scheme ever taken the trouble to reckon up how much a case of scarlet fever, sent out of hospital before the full period of infection is over, may cost the community? The obstructive managers are penny-wise and "pony"-foolish.

The amalgamation of the forces of the Great Northern Hospital with those of the proposed new Central Hospital for North London was successfully effected at the meeting held on Saturday last, under the generalship of the Duke of Westminster. The name, constitution, and mode of government of the new hospital, were severally agreed upon; and a building fund was opened, which, with the funds already at the disposal of the Great Northern Hospital, will at once enable the committee to proceed to negotiations for securing a site for building operations. The necessity for increased hospital accommodation in the northern districts formed a fertile theme for all the speakers, and must have duly impressed the large and attentive audience. No more satisfactory means of meeting this want could be found than in the cordial union of the practice and traditions of an old established institution with the vigour and vitality of a local association, fully pledged to carry to a successful issue the undertaking which they have initiated.

Whilst urging the claims of the new Hospital upon the dwellers in North London, the Marquis of Salisbury took occasion to observe that the subject was not one with which he himself was specially familiar, and his subsequent remarks upon the question of paying-wards will no doubt be regarded as sufficient illustration of the truth of this confession. With a deeply-rooted conviction of the superiority of the medical attendance given in hospitals to the average medical attendance given anywhere else, it has always appeared to him "rather hard that the more well-to-do classes of the community are shut out from the best medical advice, treatment, and attendance that can be obtained," owing to the fact that hitherto no opportunity has been given them of enjoying such attendance, in consideration of small sums paid to a hospital committee! We sincerely trust that the governing body of the Great Northern Central Hospital, whilst duly appreciative of the support of the noble marquis, will pause before adopting the principle shadowed forth in his speech. The abuses of hospitals and of the gratuitous services of honorary physicians and surgeons are already sufficiently numerous, without the introduction of a system which would be a direct incentive to wealthy, but unscrupulous, persons to profit by the advantages intended solely for the classes below them, and which would react most unfairly upon general practitioners in the district from which such persons would come. The establishment of pay-wards or a pay wing, or in plainer words, the establishment of a medical hotel, in connection with the free and general hospital, will no doubt prove a useful source of income to the latter, but we may confidently assert that the gratuitous services of the medical staff will be reserved for the hospital alone.

Dr. George Paddock Bate, in his annual report on the sanitary condition of Bethnal Green for the year 1882, remarks that there are no less than three disused cemeteries within the boundaries of his district, in addition to the graveyards attached to the various churches. Even at the time when intra-mural interments were abolished by law these cemeteries were very full of bodies, and, in the case of at least one of them, several attempts have been made to let the ground on a building lease. Recently a speculator has announced his intention of erecting, on the Peel-grove Burial-ground, a block of industrial dwellings for the accommodation of 400 persons; he proposes simply to lay a bed of concrete, and to build upon that without removing the remains. If this be permitted, Dr. Bate observes, subsidence of the ground will certainly take place from time to time, creating fissures even in concrete foundations, whereby not only will the stability of the houses be endangered, but noxious emanations will arise from the mass of putrefying human remains below. It would seem from Dr. Bate's report, that

nothing can be done to prevent owners from building upon disused burial-grounds, except under the by-laws of the Metropolitan Board of Works, unless human remains are actually disturbed; and in this case no remains are to be disturbed. And further, from some legal quibble, it is questionable whether the Board's by-laws can be put in force in this instance; should the speculator determine to proceed with his project, the matter will, Dr. Bate adds, probably become the ground of an action at law; and should the decision be adverse to the parochial authorities, they will still have the power, when the houses are finished, to have them closed as unfit for human habitation, under the 13th section of the Nuisance Removal Act. Nevertheless, it is much to deplored that Acts and By-laws are drawn in such a manner as to render the violation of all sanitary laws, as in this instance, in any way possible.

The Medical Faculty of the Vienna University at its last meeting had a warm debate as to who should be recommended to the Minister for election to the second anatomical chair. Prof. Langer, in his report on the eligible candidates, while expressing himself in the warmest terms as to the abilities and acquirements of Prof. Zuckerkandl, of Gratz, recommended that his name should only be sent in *secundo loco*, and that Prof. Zoldt, of Prague, should be placed *primo loco* on account of his great anatomical talents, and because the services he had rendered at Prague, by the construction of the great anatomical institute there, indicated the importance of his transference to Vienna, where a second anatomical institute is about to be erected. Prof. Albert maintained that Prof. Zuckerkandl's merits were so high that the two candidates should be retained *ex æquo*, but his motion to that effect was lost, obtaining only six votes against fifteen given for the report.

In an article in the *Allgemeine Med. Zeitung*, Dr. B. Kraus, the editor, discusses the question, "Whether the sons of poor men should study medicine?" in reply to a contemporary who had declared that medical education had become so costly that none but the rich could afford it. Dr. Kraus, speaking specially of the Vienna School, declares that the fear is groundless; and first he recites the names of the recent and present professional staff, in proof of what may be done by poor men's sons. Certainly the list is a noble one, and well worth transcribing. He mentions Rokitansky, Skoda, Hyrtl, Arlt, Oppolzer, Ludwig, Pitha, Schuh, Stellwag, Jäger, Albert, Hoffmann, Langer, Brücke, Bamberger, the two Brauns, Späth, Wedl, Schneider, Nothnagel, Billroth, Scanzoni, Linhart, Jaksch, Hasner, Gruber, Auspitz, Ultzmann, Kaposi, Neumann, Blasius, Kundrat, Schlager, Pollitzer, Stricker, Leidesdorf, Schroff, Zuckerkandl, Meinert, Scheithauer, Zeissl, and Schenk, none of whom were blessed with wealthy parents, most having risen from the poorest and most needy circumstances. Nor is it otherwise with the well-known clinical professors—Schnitzler, Benedikt, Monti, Winternitz, Oser, and Bandl. In fact, the sons of the wealthy manifest no eagerness to face the discomforts of a medical student's life; and were it not for the sons of poor proprietors, school-masters, and tradesmen, the supply would run short. If the expenses of education have increased too much to admit these, they will have to be lowered by a different mode of payment of the professors; and the present power which the Vienna Medical Faculty has of admitting poor students, under the name of *Berufenen*, is not likely to be abridged.

One of those melancholy deaths which from time to time occur to young practitioners while bestowing their care on the subjects of diphtheria, has just taken place at St. Petersburg. Dr. G. A. Popow, one of the assistant physicians of Prince Peter von Oldenburg's Children's Hospital, while engaged in examining the throat of a bad case of diphtheria, received on his lips and face some of the secretions from the child's mouth. In spite of the most careful cleansing, he was seized next day with shivering and the first symptoms of an attack of diphtheria, which within five days proved fatal.

The entire number of students at the Berlin Universities during the present winter session amounts to 4,635 (as compared with 4,062 last summer session); and exceeds the number entered at Leipzig (3443), which, for several years past, has been a formidable rival to Berlin. The students belonging to the Medical Faculty amount to 898 matriculated students (774 in the summer session), to whom must be added 228 pupils of the Military Medical Institutions. So large an attendance of students has never been known at Berlin, and the unexpected number has taxed the hitherto sufficient space in the Anatomical Institute, as it has also the supply of bodies for dissection, especially as at this period a large number are required for the State examinations.

Dr. Koch has sent in a further report of the proceedings of the Commission of which he is the leader, dated Calcutta, December 16th. He states that he and his colleagues have been provided with every facility for following out their investigations in the Medical College Hospital at Calcutta, and he details the experiments which he is about to undertake towards the elucidation of the question. The next report will presumably contain matter of greater importance.

The numerous accidents which have occurred from football in the United States have induced vigorous action on the part of the authorities of Harvard College. The *Boston Medical Journal* states that Prof. Norton, the chairman of the committee on athletics, has issued a report in which he severely stigmatizes the manner in which football is there played, leading to a "manly if rough sport degenerating into brutal and dangerous contests." According to certain of the rules of the American Intercollegiate Association, it would seem, he says, that a "spirit of fair-play is not expected to govern the conduct of all the players, but that the spirit of sharpers and roughs has to be guarded against." The

Association has consented to modify the rules objected to, the amendments have been approved by the Committee of the Faculty, and the prohibition of the intercollegiate games has thus been averted. The Harvard Faculty has, moreover, appointed a medical director of the gymnasium. It is further under consideration to appoint another officer well acquainted with all athletic games, and having a knowledge of the laws of health, whose rank and remuneration will be equal to those of the instructors of the college. In his hands will be placed what it is hoped will be a wise and temperate control of the active athletic sports. "With the hearty co-operation which should exist between the medical directors of physical culture and the not necessarily medical man who superintends the domain of athletic contests, there should be a maximum of all the good effects of strength-developing sport and a minimum of the overtraining and overstraining that have been the bane of such contests."

In March, 1882, a prize of 1,000 dollars was offered by a benevolent American for the best essay on "the probability of the Discovery of a Cure of Malignant Disease, and the line of study or experimentation likely to bring such a cure to light." Six essays—all in the English language—were sent in, but the judges decided that they were none of them worthy of the prize. We have not heard that another competition has been opened for the thousand dollars, but in any case we fear the prize will go a-begging, like the celebrated French prize for the discovery of a cure for diphtheria.

At the Quarterly Meeting of the Directors of the Naval Medical Supplemental Fund, held on the 8th instant, Sir W. N. E. Smart, K.C.B., M.D., in the chair, the sum of £86 was distributed among the several applicants.

The Parkes Museum, we regret to hear, is much in want of funds, to carry on and extend the valuable work for which it was instituted. In any other country it would be subsidised by the State, but in England such institutions have necessarily to depend largely on the fluctuating support of annual members, and wealthy people are too short-sighted to feel much interest in a project, the benefits of which are not immediately realisable. But the medical profession have not this excuse, and we feel sure that the claims of the Parkes Museum have only to be brought home to them with sufficient insistence, to ensure their support. When the State bestows its titular honours, it takes care that money is forthcoming to back them up, and science, having done its best in Dr. Parkes' case to make up for the neglect of him by the State, should not allow itself to be stultified as a fountain of honour, by letting its peers, so to speak, lapse into paupers.

The useful work which the Museum is doing, in an educational sense, is evident from the valuable lectures already delivered, as well as from the following list of those that are still to be given :—On January 31st, at 5 p.m., Mr. H. A. Darbishire, F.R.I.B.A., the architect to the Peabody trustees, will give an address on the burning question of the day—"Artisans and Labourers' Dwellings;" on Tuesday, February 12th, at 5 p.m., Mr. J. P. Seddon, F.R.I.B.A., will give a lecture on the "Ventilation of Theatres," Mr. George Godwin, F.R.S., will take the chair at this lecture; on Thursday evening, February 28th, at 8 p.m., the question of the "Purification of the Air in Living Rooms and Sick Wards," will be dealt with by Dr. H. C. Bartlett, F.C.S., taking up the question of the general principles involved, while Dr. Richard Neale will give a description of the structure and mode of action of his "Chemical Lung;" on Thursday, March 13th, at 5 p.m., Dr. Henry Veale, Deputy Surgeon-General, whose name is well known in connection with Lord Wolseley's expedition to Egypt, will give a lecture on "The Organization and Management of Field Hospitals;" on Thursday, March 27th, at 8 p.m., Mr. Watson Cheyne will give a practical demonstration of micro-organisms, illustrating his remarks by microscopical preparations and photographs. The final lecture of the session will be delivered on Thursday, April 24th, at 5 p.m., by Dr. John A. Voelcker, of the Laboratory of the Royal Agricultural Society of England, who will take up the subject of milk.

The intimate connection between affections of the eye and the generative organs in women, though on several occasions, of late years, insisted upon by ophthalmic surgeons, has never hitherto been demonstrated in so conclusive a manner as it has been by Mr. Priestley Smith, in the *Ophthalmic Review*. To remove both ovaries and Fallopian tubes from a young married woman is not an operation that should be lightly undertaken, and when it is announced that the operation was performed with a view to prevent the patient from going blind, there are not a few, probably, who would be ready to denounce such a measure as unjustifiable. Yet such is the proceeding described by Mr. Priestley Smith, carried out with entire success up to the time of reporting the case. The facts of the case very briefly were, that the patient, a young married woman, æt. 24, had suddenly and completely lost the sight of the left eye after a fainting seizure dependent upon, or associated with, some uterine or ovarian disorder. On subsequent occasions the right eye was several times rendered temporarily blind after similar attacks, after which the field of vision became permanently and considerably contracted; in the left eye the disc was somewhat white and the arteries much shrunken and mostly empty. The diagnosis of chronic ovaritis was made, and both ovaries and Fallopian tubes were removed and found to be in such a condition as to fully justify their removal. It should be mentioned that all, or nearly all, the fainting attacks were traceable to pain originating in the pelvic viscera. After the operation, the patient's progress was remarkably satisfactory; she ceased to suffer from fainting attacks, and the field of vision with the right eye again became entire. Mr. Priestley Smith puts the sequence of events as follows: Reflex disturbance of the circulation in the brain and retina through cardiac inhibition, great reduction and slowing of the blood stream

in the retinal artery and thrombosis, to which the anæmia and weakness of the heart would predispose, and he enters into a very interesting discussion as to whether the affection was due to thrombosis or embolism, pointing out very clearly the diagnostic points of difference in each condition, and giving what seem to us to be very good reasons for believing that in this case there had been thrombosis rather than embolism.

Mr. Henry E. Armstrong, medical officer of health for Newcastle-upon-Tyne, has issued a report on the increased death-rate of that town. By means of a discussion on the *extrinsic* origin of febrile disease, by essays on the whole subject of sewage disposal, on school hygiene, on ventilation, on warming, on the advantages of the half-time system of education, by digressions, quotations, maxims, truisms, and by the trite commonplaces of the sanitarian, the author has succeeded in expanding matter, which might have advantageously occupied a few pages, into a volume to which we should have been tempted to apply the author's phrase, "confused, vague, and elusive," if it were not for the interesting and instructive facts to be gleaned from the pages and tables by those who have the industry and courage to gather them, and were it not for evidence that Mr. Armstrong is a fearless, a good, and a conscientious officer, who calls a spade a spade, and a disease centre "a fever den," and whom the owners of property daunt so little, that he hesitates not to publish a map, with the dark spots in his district surrounded by coloured borders.

Newcastle-upon-Tyne has a population of 145,369, living in 20,264 houses; of these only 10,750 houses are provided with closets, the remainder use the primitive constructions found by Captain Cook in his first voyage to New Zealand. The middens are calculated to be 20,000 in number, and if united would present an area of 3,200,000 square feet. One hundred and forty-five slaughter-houses, dirty, badly supplied with water, most of them defective in construction, discharge, with few exceptions, their blood and liquid refuse into the sewers; 156 cow-houses in which "a water tap and hose comes as a surprise," and in which "the dung-pits are commonly large and uncovered, so that their already sloppy contents are exposed to the action of sun, rain, and wind," mingle their effluvia with the emanations of 49 pig-sties. Over all floats an atmosphere polluted with smoke from factories, steam-mills, breweries, bakeries, and river steamers. Under these circumstances it is refreshing to find that the Anglo-Saxon is so tenacious of life that the death-rate of Newcastle-upon-Tyne is after all but 23 per thousand; it would have caused no astonishment had the figures been reversed.

The inward rottenness of the prosperous city being thus revealed, the health officer and his committee are losing no time in attempting to remedy the old abuses; a house to house visitation has been initiated, twelve additional inspectors having been appointed for this purpose; and we cordially endorse the recommendations of Mr. Armstrong in the matter of public abattoirs, in the substitution of ash-closets for the old middens in the tenement dwellings, and in the necessity of prompt and immediate action for the suppression of the many-headed filth dragon.

The fact that the authorities of Guy's Hospital have found it advisable, if not necessary, to set apart beds for paying patients, and to extend the system of payment to all out-patients, tells very significantly which way the current is setting, and we may expect that the example of such a solid and time-honoured institution will be followed without long delay by every hospital in the metropolis. No one can object to the universal adoption of this system, except possibly the publicans, whose tills will suffer in proportion as the hospital cash-box gains; but the drink margin of the working classes is in the aggregate so enormous, that the hospitals would be able to take a large bite without seriously diminishing it. Nor is it likely that the medical practioners in the neighbourhood of hospitals will greatly sufler. For though many patients will no doubt seek advice at a paying out-patients' department, who would have been deterred by the scramble, and the idea of accepting charity, involved in attendance at a free hospital; yet, on the other hand, there are many patients so curiously constituted, that the chief attraction to them, of hospital treatment, is its gratuitous character. These and many others, when they find that they cannot visit a hospital without putting their hands in their pockets, will, no doubt, prefer recourse to the practitioner, whose surgery is open at all hours, and whose fee is not so very much in excess of the pence demanded of them at the hospital. But the chief advantage of a universal system of paying out-patient departments, would be that it would, for the first time, render possible the establishment of a sound provident dispensary system, which is, no doubt, the coming system of lower class medical relief.

A paradoxical case is reported from Dublin. A police sergeant, who had been trained under the St. John Ambulance Society, found in the street a woman who had fallen and broken her right leg. He immediately set to work to construct a temporary splint out of two batons and his duty bands, and removed her to the hospital. Batons are, no doubt, more usefully employed in binding of broken bones than in breaking sound ones, and the same modification of function might advantageously be extended to the shillelagh.

A report has been in circulation that the police, foiled in their attempts to solve the Stoke Newington mystery, have definitely come to the conclusion that the deceased was not murdered, but committed suicide. It is said that they have become cognisant of certain facts in Tower's life which support the theory of suicide, and that Mr. Bond's positive statement that the case was one of homicide has been severely criticised by "several prominent members of the medical profession." The report has been contradicted, and it bears upon it evident signs of improbability. No member of the profession, we imagine, would be bold enough to come forward as an antagonist to Mr. Bond on the

ground which he has specially made his own, and certainly not without having had as good an opportunity of studying the post-mortem appearances of the case as Mr. Bond has. The theory of suicide, said to be started by the police authorities, involves a slur, not only on the deceased, but on one of their own surgeons.

Fortunately the "Mysterious Case of Poisoning," chronicled in the papers this week, has for mystery only the questions of how and why the poison was employed. The public mind is spared the shock of discovering that some new poison exists, which can be detected only by physiological tests. Whether or not the deceased intentionally took the arsenic does not appear in evidence; all that is certain being the fact of death preceded by symptoms of irritant poisoning, and the detection of arsenic after death.

On Friday the 18th instant, the Thames police magistrate had before him what the *Daily Telegraph* rightly characterises as a "shocking case." A man, whose daughter lay ill with small-pox, and was about to be taken to hospital, was warned by the police inspector not to remove anything from his house or shop. The next morning the inspector found that a large stock of newspapers, which had been only a few yards from the daughter's couch, had been removed in the interval, and a vacant room had been let to a woman with four children. For thus running his head against the law the defendant was fined five pounds, and locked up in default of payment.

Our brethren in Napier, New Zealand, have lately been monopolising the attention of the Chief Justice and a jury of four, in the supreme court for a couple of days. A young woman brought an action against a practitioner for unskilful and negligent treatment. He had attended her for fractured leg during three months, and she had consulted him afterwards, at intervals, for a year from the time of the accident, when being still unable to walk, she went into the hospital, where an ununited fracture of the fibula was recognised, and the ends of the bone were removed with a good result. The tibia had united satisfactorily. The defendant argued that the fracture of the fibula must have taken place subsequent to his treatment of the case; and four medical men gave evidence that the treatment that had been adopted had been what was right and proper, though they could not agree with the defendant that the fibula had not been broken at the time of the original accident. In the end the jury found for the plaintiff, awarding her £175, or rather more than half what she asked for. We fancy that our own hospitals would furnish material for a good deal of this sort of litigation, if the physicians and surgeons lent their countenance to it.

In a short retrospect on the health of the Borough of Huddersfield during the year 1882, Dr. J. Spottiswoode Cameron, the medical officer of health for that locality, has published the result of his observations on the mortality amongst young children in this district, which, for the period under notice, was considerably above the average of the previous five years. During the greater part of 1882, Huddersfield suffered from an epidemic of measles, and this was followed by an unusually high mortality among young children; the rapid spread of this epidemic coincided, Dr. Cameron points out, with a somewhat high barometric pressure, an increasing temperature, a considerable variation of day and night temperature, and a scarcity of rain. It appeared to him that the poison of measles, which had been present in a less amount earlier, was prevented, by the heavy atmosphere and the absence of wind during some weeks, from getting freely away from the close courts and yards in which so many of the patients lived. The air in these courts lacked the wholesome washing of the rain, and the poison, instead of being carried away down the drains, or driven away by the winds, was kept active by the warmth of the day, slightly condensed by the chill of the night, and so spread rapidly amongst those susceptible to its influence. Again, whooping-cough, like measles, affected chiefly the very young children; it was specially fatal in the first quarter of 1882, but gradually disappeared later on. It is only fair to add, that the death-rate of Huddersfield differed only by a decimal point from the average death-rate of the twenty-eight large English towns during 1882, and Dr. Cameron is hopeful of securing a higher position for his borough in the relative table of succeeding years.

As Emeritus Professor of Clinical Surgery to the London Hospital Medical College, Mr. Jonathan Hutchinson, F.R.S., will deliver a course of six lectures in the anatomical theatre of the college, at 2.45 p.m., on Wednesdays and Fridays in the first three weeks in February, beginning on the 6th.

The first thing that the Romans did, when a place which had an unfortunate name came into their possession, was to give it a good one, in order that the deities might no more be prejudiced against it. The authorities of Exeter, as those who live n that ancient city are aware, have imitated this excellent custom, and with the view of removing local predispositions, have euphemistically called their Fever hospital the "Exeter Sanatorium." When a dog, however, has a bad name, it is said to be waste of time to give him a better one, and it is to be feared that the same may apply to a locality or institution. The air of Maleventum did not probably become more fragrant when its name was changed to Beneventum, or if it did, this example of easy sanitary reform has certainly been lost on modern Italian cities. And we do not suppose that the Exeter Sanatorium will be any the less shunned by the ill-instructed populace than it would have been if it had borne the name of Fever hospital. "Hospital" is in itself a word of noble descent and connections, but there is none in the vocabulary more generally detested by the lower orders. And the Exeter authorities will be fortunate if their new word escapes the ruin in character, which is the lot of most words originally used as euphemisms.

The institution in question has been fairly active during the past year, as its promptly-published report testifies. Eighty-one cases of zymotic disease were under treatment during 1883, of which six proved fatal, four from typhoid, one from diphtheria, and one from small-pox. The total number of cases of typhoid treated was 28, so that the mortality was 14·3 per cent. Of the twenty-five cases of scarlet fever not one proved fatal. Of the twelve small-pox cases none had been re-vaccinated, but ten had marks of primary vaccination. Two had no marks, and of these one died. The report states that the Sanatorium is becoming more widely appreciated in the country districts, as evinced by the large increase of cases from that source. The value of such an institution is out of all proportion to the actual work done in it, for every case timeously removed to it, like the proverbial stitch, saves the nine which probably would otherwise have to be treated outside. The Sanatorium no doubt materially diminishes the duties of Dr. Woodman, the energetic officer of health for Exeter.

The eighth annual report of Dr. Stevenson to the Paddington Vestry on the health of the locality for the year 1882, contains nothing which can be classed as of more than average importance. Dr. Stevenson is apparently content to record the usual statistics, leaving the figures to speak for themselves. We find, therefore, that during the year under notice, 2,904 births and 1,948 deaths were registered in this parish, giving a ratio of 26·8 per 1,000 for the former, and 16·3 for the latter; with the exception of the two preceding years, when the death-rate was 15·7, the rate of mortality is less than that recorded in many previous years. The most fatal of the zymotic diseases proved to be measles and whooping cough, whilst the mortality from scarlet fever was less than in any one of the eight preceding years. No death occurred from small-pox, and only six cases of this disease came to the notice of the authorities during the whole twelve months. The mortality from typhus, and from other, or ill-defined forms of continued fever, was far below the average, and, owing to the temperate character of the summer, the deaths from diarrhœa only numbered 44. We may take it, from these few facts, that the sanitary condition of the parish of Paddington during the year under notice was satisfactory, and nothing exceptional occurred calling for any special comment.

On Saturday last, William Wallis, herbalist, was committed for trial on a charge of manslaughter, by administering lobelia as a medicine for a chest complaint. More than twenty years ago another herbalist, by the same insane method of treatment, all but succeeded in cutting off twenty years of a life which England could ill have spared. In his delightful biography of the late Professor Palmer, Mr. Besant tells us that, when Palmer was a young man of nineteen, he was seized with symptoms of consumption, and his case was declared hopeless. Given over by the faculty, he was persuaded to follow the treatment recommended by a Cambridge herbalist, which consisted in taking a single very strong dose of lobelia. The result was that he "was first seized with a violent attack of vomiting, then a cold chill laid hold of his feet and slowly mounted upwards; it froze his limbs, which he could no longer move, and struck his heart, which ceased to beat (?), and his throat, which ceased to breathe. They had sent for a doctor by this time. 'I felt myself,' he said, describing this experience—'I felt myself dying; I was being killed by this dreadful cold spreading all over me. I was quite certain that my last moments had arrived. . . I saw the doctor feeling a pulseless wrist, watch in hand; the cold dews of death were on my forehead; the cold hand of death was on my limbs. Up to my lips, but no higher, I thought I was actually dead, and could see and hear, but not speak, not even when the doctor let my hand fall upon the pillow, and said solemnly, 'He is gone!'" He recovered, however, not only from the poison, but from the disease, and to the end of his life the "lobelia cure" had in him a firm believer. Professor Palmer is admitted by all who knew him to have been of a highly nervous temperament, and it would be difficult to say how much of his apparent death was due to lobelia and how much to "nerves."

A very careful and interesting health report is that for the Borough of Birkenhead for the year 1882, compiled by Mr. Francis Vacher. The district in question has now been for some time under the watchful supervision of its present health officer, and it is certainly not too much to say that its improved sanitary condition is mainly the result of his exertions. The number of births registered in Birkenhead during 1882 does not compare unfavourably with the number recorded in recent years; but the decrease in the mortality, which was maintained from 1878 to 1881, was not continued. Nevertheless, Birkenhead, which was last year included by the Registrar-General for the first time in the list of the great towns of England, will be found, Mr. Vacher shows, to be the highest but ten as regards its birth-rate, and the lowest but three as regards its mortality. Of the 1,718 deaths from specified causes registered in the borough during 1882, 319 were ascribed to zymotic diseases; but it is a source of satisfaction, the report adds, to be able to record that another year has passed without any fatality from small-pox, an exemption which has been maintained since 1877, the year when the disease was epidemic in the locality. Indeed, so far as the sanitary authority have been able to ascertain, there has not even been a case of small-pox in the borough during the past year. Birkenhead obtained an Act for the compulsorily notification of infectious diseases in 1881, and, according to the report, the working of this piece of legislation during the year under review has been satisfactory; 962 cases were notified by medical practitioners, and 25 by the school attendance officers, the occupiers of houses, the relieving officer, the inspectors, and, in a very few instances, by the registrars.

On Monday night a complimentary dinner was given to Professor Sir Richard Owen, K.C.B., by his late colleagues in the service of the British Museum In returning thanks for the toast in his honour, Sir

Richard Owen spoke of his labours at the Royal College of Surgeons, and expressed gratification that in the course of his duties there he had been able to extend the usefulness of the Hunterian collection, partly by valuable additions, and partly by the lectures he had annually delivered.

The late Sir Wm. Siemens has bequeathed £2,000 to the German Hospital at Dalston, and £1,000 to the Tunbridge Wells Infirmary.

Dr. F. W. Barry has contributed to the Local Government Board a complete sanitary history of the Tynemouth districts, both urban and rural, and has supplemented the same by a series of reports—nine in number—on the urban districts immediately adjoining. The information thus acquired, shows the sanitary—or perhaps it would be more correct to say the insanitary—condition of that particular locality, and, without considering each of these nine reports separately, it will be sufficient to observe that the defects existing in one district were conspicuous in all the others. The uncovered midden privy constitutes the usual form of closet accommodation, and this is generally so constructed and managed as to give rise to very considerable nuisance, both in storing and removing excrement. Dr. Barry has noted, in two or three cases, the ridiculous arrangements made by the sanitary authorities with their health officers; in the Howdon Urban District, the medical officer of health receives a salary of £7 10*s.* per annum. He lives twenty-six miles from the scene of his supposed labours, but reports monthly as to any cases of infectious disease which may have occurred; as, however, there is no provision in this district for isolation of patients, or disinfection of infected articles, it is impossible for him, the report remarks, to take any effective action for limiting the spread of epidemics when they occur. A still more remarkable course is that pursued in the Whitley and Monkseaton district; in this case, the medical officer receives an annual retaining fee of three guineas, with an additional fee when called in; but, up to the present time, there has been no demand for his services. He receives no returns from the Registrar of Births and Deaths; has never officially inspected his district, or attended a Board meeting, or made a report. Dr. Barry has spent an immense amount of valuable time in examining into and exposing the shortcomings of the Tynemouth neighbourhood; but this in itself is of small advantage, unless some power existed to compel the different authorities to carry out his judicious recommendations.

PATHOLOGICAL EXPERTS.

The whole subject of the existence, efficacy, machinery, and mode of proceedure of the coroner's court has been so constantly under discussion, that we may justly assume it to be a question in which no little interest centres. The matter is in fact one in which medical men have a very real and personal concern. It is upon their dicta, as a rule, that the whole decision and verdict must hang. Many have come to the apparently logical conclusion that the office of coroner is one which ought to be held by medical men, since they alone are able to weigh the value of the technical issues which are placed before the jury. It is not our present purpose to discourse upon this head, nor even to join issue with the *Boston Medical and Surgical Journal*, which, not so long ago, tersely disposed of the question by decreeing that "the coroners must go." Our object is to bring before our readers the necessity which exists that the coroner's court, as at present constituted, should be assisted in its deliberations, in every case of enquiry as to the cause of death, by the trained evidence of skilled pathological experts. As matters are now arranged, it is well known that any local medical man may be both summoned by the coroner to give evidence, and ordered by him to perform, and report upon, a post-mortem examination of the deceased. We do not believe that the ends of justice are furthered to the best advantage by this means; we believe, in fact, that it is opposed to the true interests both of the public and of the profession. With all, the sole desire in the matter must be the elucidation of the truth, and we think that professional opinion is now ripe to admit that neither the public interest, nor our knowledge of morbid anatomy, is furthered to the greatest possible extent by the present method. A lurid light is thrown from time to time upon the whole subject of medico-legal investigation by such crucial cases as that which was lately the subject of such prolonged consideration at Liverpool—cases in which the whole possibility of the discovery of the truth turns upon the skill with which the post-mortem investigations are conducted. In the interests of all, then, we maintain that, in these days of specialism, a distinct specialty ought to be made both in town and country of the conduct of medico-legal post-mortem examinations.

It must be sufficiently obvious to any one who understands the subject, that a very practised and special skill is requisite for the discovery of an unknown cause of death by the autopsy alone. Few medical students have had time, opportunity, or inclination for the attainment of such skill, and fewer still have had chances (after entering the vortex of active professional life) of keeping up and improving such practical pathological knowledge as they may have obtained in the post-mortem room of their hospital-school. It is of course the fact that in a large proportion of those cases in which a post-mortem examination is ordered, the death is, as a fact, due to natural causes, or to the undoubted effects of some accident. In most of these cases the post-mortem researches and conclusions are directed and influenced by obvious facts which concern the life and mode of death of the deceased. It is not in these cases, perhaps, that the result of unskilled examination is of most serious import. The truth in such cases is probably determined with sufficient accuracy, and the medical witness is able to satisfy himself, the jury, and the public, that the morbid changes which he has discovered are in fact enough to account for the death under consideration. Even in these cases, however, the ends of science are but poorly served by the hasty and general conclusions too often arrived at. The post-mortem examination should be not only a thorough clearing up of the cause of death, but a definite scientific contribution to our store of pathological facts. Too often, we fear, it is of no such

value. The examination is performed by a man skilled indeed in the practical exercise of the healing art, but with no special aptitude for noting the minute and often obscure evidences of disease in the dead subject. It is performed by him often under great disadvantages, unwillingly, inconveniently, not awkwardly or perfunctorily, but at least without any special desire in the matter except to discover a sufficiently valid cause of death in the shortest possible time. The evidence of the medical witness does occasionally convey this impression, if not to the public, at least to the professional observer. What proportion of practising medical men, may we ask, are able to examine critically the brain in the recently dead subject—its convolutions, sinuses, and centres being all passed under review—so as to determine the absence or presence of extravasation, embolism, or thrombosis, as a cause of sudden death? The vague and inadequate causes of death sometimes registered are too often unsatisfactory to any skilled on-looker. Thus Niemeyer naïvely writes, with reference to the frequency with which post-mortem "congestions" and "engorgements" are described, that "one would conclude from some of these observers, that the body actually contained more blood after death than it had done before." Thus, while we do not assert that the cause of justice and of scientific truth is, as a matter of fact, often mis-served by the present process, we do believe that there is a constant possibility that it may be so mis-served, and certain cases which from time to time throw light upon this unsatisfactory subject would lead us to suppose that the actual cause of death does, every now and then, elude the research and skill commanded under the present system. Sure we are that a very special, well trained, and well-sustained skill is required for the due intelligent performance of post-mortem examinations, and for basing what may well be most important conclusions upon their results.

We have said that the present system is opposed to the best interests, not only of the public, but of the medical profession itself. And in this we think the majority of thoughtful general practitioners will agree with us. They are willing enough to admit that their skill and experience do not tend to the most effectual performance of medico-legal autopsies. They are, of course, ready and eager to take every opportunity of improving their acquaintance with the processes of disease and death. But they are ready also to allow that, for the furtherance of pathological exactitude, it would be better that the bodies of persons who have died under suspicious circumstances, or who have not been seen during illness by any qualified medical man, should be examined by some skilled expert. Such an expert would assuredly perform the examination with more ease, more confidence, and more scientific accuracy in result than they, amid the duties of active professional life, can aspire to. We have so often heard medical men complain that the performance of a post-mortem examination, by the coroner's order, is "the hardest work for a guinea" that they are ever called upon to perform, that we think there are few who would not be willing to hand the task over to a skilled authority. It is certainly no facile or pleasing task for a general practitioner to perform, single-handed it may be, and in the depth of the country—with no help or conveniences worth mentioning, at the sacrifice of valuable time, and to the detriment of his legitimate course of work—a post-mortem examination of a body unknown. For this examination but little credit can be obtained if successfully and honestly conducted, and much of opprobrium and discredit should the cause of death, so hardly sought, be misstated, or elude his observation. It is true that in cases of poisoning, actual or suspected, it is the recognised custom to have the requisite analysis made by a skilled chemist. We of course cordially approve such precaution, and only contend that the ends of public justice and pathological knowledge would be better served if the whole examination and research for the cause of death—natural, accidental, criminal, or suicidal—were made by a trained and well-practised expert. We have observed above that the legitimate course of work of the practitioner is interfered with by the present method, and in this we refer not only to the necessary loss of time, but to the actual danger which may accrue, for instance, to the lying-in patients of the busy general practitioner when he is ordered, without respect to his convenience or their safety, to perform a post-mortem examination, from which septic and lethal infection may well be conveyed to the bedside of the unsuspecting patient.

What, then, do we recommend as a cure for a state of affairs which we believe to be so unsatisfactory? It seems to us that the problem is capable of a tolerably easy solution. The whole difficulty would be met by the appointment, in every coroner's district, of one or more experts, of proved and well-authenticated skill, by whom all post-mortem examinations, made under coroner's order, should be conducted. The payment of these experts might be by fees or by salary, but should be sufficient to act as an attraction to men who would thus abstain from general practice, and devote themselves to the scientific branches of their profession. It is probable that in many districts it might be found well to unite the duties of medical officer of health, public analyst, and public pathologist in one and the same highly educated specialist. We can call to mind, at once, several cases in which the medical officer of health of a district is distinctly and obviously qualified, as a man of the requisite knowledge and skill, and having both time and inclination so to add to his duties. The practitioner's evidence would, of course, in many cases, still be forthcoming, and his knowledge of the previous history or illness of the diseased would be often a valuable contribution. But the actual post-mortem examination, and responsibility for its accuracy and completeness, would be the part of the public officer, and to him both the public and the profession would look for the advancement of truth and knowledge. In thus placing this subject briefly before our professional readers, we have little fear that men of weight or culture will disagree with us. At any rate, we may confidently predict that, as reforms, social and medical, become (with revolving years and the growth of a more thoughtful and practical generation) matters not only of theory but of accomplished fact, this office of pathological expert will be one as to which a future age will wonder only how we did so long without it.

THE CASEBOOK IN THE FAMILY.

It will be a matter for surprise if the alert and imaginative alarmist, who from time to time startles us in the pages of the *Lancet*, does not discover that Mr. Galton, in publishing his "Life History Album," is preparing a new peril for the British infant. We shall probably be asked whether we are not satisfied with ruining our children, when grown up, with plays, masquerades, and pantomimes at home, and with preposterous exercises and examinations at school, that we must needs invade the nursery, and rob them of the few short years of happy objectivity that are still left them. Half the unhappiness, and much of the insanity, in the world, we shall be told, is caused by people thinking about themselves, and to begin to turn a child's attention upon himself from the very moment when he first "learns the use of 'I' and 'me,'" to weigh him, to measure him, to test his senses, his strength, his intelligence, and his artistic capacity, to be ever on the watch to record his slightest peculiarities and symptoms—that we shall be told, is the very way to turn him either into a lunatic or a hypochondriac. There would, it is true, be some slight foundation for such a protest. The children of the present generation are no doubt given a fictitious sense of their own importance by the indulgences of home and the competitions of the schoolroom, and their egoism will not be diminished by their having their cases taken from time to time in the methodical way demanded by Mr. Galton and the collective investigation committee of the British Medical Association. But the effect on a child of such a systematized watchfulness will depend entirely on the good sense of the parent. A sensible mother—for it is amongst women no doubt that Mr. Galton will find his chief allies—would of her own initiative keep her children as ignorant as possible of the observations being made upon them until the time came for them to take their casebooks under their own charge. As, however, it will probably be the foolish and over anxious mothers who will most readily take up with this new idea, we should like to have seen a special caution as to the inadvisability of drawing children's attention to themselves, placed prominently in the preface to each volume.

With this proviso, the usefulness of Mr. Galton's book is beyond all question. We are a little doubtful as to the possibility of working out any reliable scientific generalizations from the mass of records with which he will be flooded. They will probably at best merely suggest hypotheses, for subsequent careful investigation. The faculty of accurate observation is so rare, and it is given to so few untrained observers to be able to disentangle their inferences from their facts, that we should imagine that the large majority of Mr. Galton's data will be absolutely untrustworthy. Still there are certain advantages connected with his proposal, entirely apart from its scientific promise. The album will be a valuable means of education to everyone who undertakes to use it. There is no means of self-culture at once so useful and so neglected as that of recording observations. The part of the medical student's training which is most beneficial to him, and which serves most to differentiate him from all individuals taught in other ways, is his course of case-taking in the hospital wards and post-mortem room. The only way by which most men can learn to register impressions correctly in the brain, is by making a practice of registering them on paper. Observers not trained in this way are for the most part inaccurate, slovenly, and incomplete observers. Physicians find that even their best clinical clerks can seldom keep the record of a case from first to last in such a way that their notes shall present a satisfactory picture of the case in a scientific point of view; and where a clerk, with his special training, fails, it is hardly to be expected that the average British mother and father will succeed, however conscientious their endeavours. Still, whatever be the value of such records, in a scientific light, there is no doubt that Mr. Galton has provided, for those who undertake to follow his plan, a means of education which they could gain in no other possible way. For this purpose, and for this alone, we think the introduction of the casebook into the family worthy of every encouragement from the medical profession. Individually the doctor may now and then find the record kept by his patient of use to him, especially if the details of previous illness have been inserted by another medical practitioner, but it is, after all, only in a small proportion of illnesses that the previous history of the patient is of supreme importance.

RECENT DISCOVERIES IN THE TREATMENT OF THE INSANE.

The lunatics of Central Kentucky have reason to be thankful that they were born in the nineteenth century and in an age of humanity, and not in the dark ages, before mercy and humanity had forced their bright way into the madhouse and the jail. The Superintendent of the Central Kentucky Asylum is a man of vigorous benevolence. He desires to say to the Board of Commissioners and to the public, that whenever an act even approaching cruelty has been detected by him, or reported to him, and it has been found to be well founded, the perpetrator of it has not been allowed to remain in the asylum one single hour. This is as it should be; there would seem to be no need for a Board of Commissioners to check the practice of an asylum that is managed on this principle, and where such Draconian severity is enforced against rough attendants. Nevertheless the Commissioners have certainly done a service to the community by showing, on the authority of this humane and benevolent superintendent, what practices are not cruel—do not even approach cruelty—and are not only legitimate, but absolutely necessary for the treatment of the insane. One of these practices is "ducking." As ducking is unknown in this country, our superintendents will doubtless be glad to be told how to perform an operation without which "it is utterly impossible to conduct an insane asylum . . . unless you get an attendant for every patient." The operation of ducking possesses all the simplicity that characterises the conceptions of true genius. Every one, when he hears it, will wonder that it never occurred to him before. It consists in strapping the hands of the patient behind him, tying towels

around his feet, placing him in a bath, "generally" on his back, and holding his head under water until he "signifies" that he will behave himself. Simple as the operation is, certain precautions must be taken, in order to ensure success. It is not sufficient merely to push the head under water; it must be held under. The precise duration of this part of the operation is not stated, and would seem to be immaterial so long as it is not too short. Unfortunately human nature is imperfect, and even in an asylum where the perpetrator of an act even approaching cruelty is liable to instant dismissal, black sheep will steal in sometimes; and it is therefore not surprising, although it is very depressing, to hear that even so mild a remedy as ducking is, like every thing else, liable to abuse; but it is encouraging to know, that in spite of this remote liability, the bathing of patients in this way is, when properly administered, "very beneficial to them." In spite of its ingenuity and thoroughness, ducking does sometimes fail; but even then we are at no loss for remedies. The resources of the Central Kentucky Asylum are far from being exhausted. We have still the towel bath at our disposal. Again we fear the conservative and unenterprising spirit of the English medical superintendents has kept them in ignorance of a remedy even simpler and more easily applied than ducking, and, it appears, still more efficacious. The towel bath is simplicity itself. "It is nothing more than confining the hands of the patient, and the feet, to keep them from kicking or striking the patient or patients assisting. A towel is dipped into water and laid over the face." Mark the striking and unlooked effect. "*It produces a sense of suffocation.*" Herein lies its efficacy. When this effect is produced, "the patient soon gives up, and is tractable." This mode of treatment has so many advantages that they are not all obvious at once. It would be tedious to enumerate them all, but we may point out the most salient, which is its economy. The Central Kentucky Asylum is entitled to the entire and unquestioned credit of introducing a method of treating lunatics by having them half suffocated by their fellow-lunatics. The treatment is as economical as it is ingenious, dispensing in the first place with the cost of attendants, and doubtless, if it is carried out thoroughly and continued long enough, with the cost of keeping patients also. These two methods of treatment are alone enough to secure the reputation of any institution, and to immortalise their originator, but they are not the only benefits that suffering humanity owes to the Central Kentucky Asylum. Strange to say, ducking and the towel bath sometimes fail to quiet the patients, and in such cases the obdurate lunatic is placed in a wire cage, which is also used for a bed—in other words, he is kept in it all night. It is sad to have to record that the proverbial ingratitude of paupers should characterise also the inmates of lunatic asylums. One of these degraded creatures, named Jansen, had the effrontery to die under this system of treatment, and an inquiry by the Commissioners in Lunacy enabled the enlightened superintendent to secure a wide publicity for his views on the treatment of the insane and the practical advantages of his methods. The public press of America does not appear to be favourably impressed by the new knowledge that they have gained as to the care and treatment of the stricken brethren in the Central Kentucky Asylum. Unfavourable and even severe comments have been passed upon the institution; but doubtless the superintendent is aware that every great innovator has to live down calumny, and that the public is proverbially unfair, fickle, prejudiced and impulsive in its approval and condemnation of men. Let us hope that the whole management of the asylum will be thoroughly investigated before some impartial tribunal, and that a just and condign punishment will fall upon those who have deserved it. One name will immediately occur to all our readers as that of the fittest person to preside on the occasion—the name of Mr. Justice Lynch.

REVIEWS AND NOTICES OF BOOKS.

CHARPENTIER'S MIDWIFERY.[1]

From the point of view of the fully-occupied general practitioner, there are no books so important and so valuable as systematic treatises which cover the whole of the subject with which they deal. It is impossible for any one at once to carry on a large practice and to read every monograph which appears: and, consequently, the busy medical man who wishes to use his spare moments to the greatest advantage in keeping himself abreast of the progress of our art, can do so best through the medium of books in which the new knowledge which is constantly being added from the most diverse quarters to the common stock, is condensed into the smallest compass; and in which, within the covers of one treatise, he can be sure of finding some information for his guidance on every part of the subject. Although to English medical men English books are the most immediately useful, yet translations of good foreign books so readily find publishers and purchasers, that the appearance of a complete treatise on any branch of medicine, though in a foreign language, is an event calling for notice. We think these considerations a sufficient reason for noticing somewhat fully the second volume of "Charpentier's Treatise on Midwifery," the first volume of which we reviewed some time since. We then expressed our opinion as to its general character and its special excellences. The second volume, which we now consider, is divided into three books. The first treats of dystocia, the second of the obstetrical operations, and the third of the pathology of the puerperal state.

The causes of dystocia are divided into the usual two classes—maternal and fœtal. In the exposition of maternal dystocia, the anomalies of uterine contraction are first considered, in a chapter which is short, containing only twelve pages, and one of the weakest in the book. The distinctive features of different forms of failure of uterine power are not at all clearly described. The material for the chapter does not seem drawn from original

[1] *Traité pratique des Accouchements*, par le Dr. A. Charpentier, Professeur agrégé à la faculté de Médecine de Paris, ex-chef de clinique d'accouchements de la faculté. Tome second. Paris, J. B. Baillière et fils. 1883. P. 994.

A Practical Treatise on Midwifery. By Dr. A. Charpentier, &c.

clinical observation: it rather appears as if the author had read various papers on the subject, not very well selected, and mixed together digests of their contents, not always in quantity proportioned to their relative importance. Some statements are so incorrect, that it is manifest that the author has not thought about them: *e.g.*, we are told that excessive energy of uterine contractions may produce prolapsus (p. 4). We know that the action of the abdominal muscles, which is so powerful an auxiliary during the second stage of labour, may force down the uterus; but how the contraction of the uterus itself can produce prolapsus, we cannot imagine. The anomalies of contraction of the abdominal muscles are considered, or rather mentioned, together with fractures of the sternum and subcutaneous emphysema, in a brief chapter which follows. We then come to the important subject of pelvic deformity, to which 200 pages are devoted. Much labour has been bestowed upon this section of the work. Each of the different forms of abdominal pelvis is described in detail, both in its anatomical and clinical aspect. The views of different authors as to the production and classification of deformed pelves are quoted, and copious references given to specimens and descriptions. The chapter is in fact a most useful epitome of the literature of the subject, the fullest, we believe, that any text book on the subject contains. In reading it we are grateful to the author for the trouble he has taken to put us in possession of so much material for our information and guidance, rather than struck with his philosophical insight or comprehensive grasp. It is profusely illustrated, both with drawings of pelves, diagrams, and full-length sketches of patients; but the wood-cuts do not do credit to the engraver, or to the printer, being often blurred and smudgy. Difficulty in labour, due to morbid conditions of the vulva and vagina, is taken next. The causes, prevention, and frequency of rigidity and laceration of the perineum, are considered at great length—at greater length indeed, as it seems to us, than the value of the materials at the author's disposal makes worth while. We have the usual abundance of quotations; but most of them are nothing but expressions of opinion, and therefore scarcely worth citing. Persistence of the hymen, tumours of the vulva and vagina, hernia, prolapsus, are very briefly dismissed. The section on thrombus of the vulva and vagina is well done; and that on vesical calculus complicating labour contains references to a number of cases.

Next in order, we have cases of dystocia, in which the obstacle is situated at the cervix uteri. First comes simple rigidity. This is treated rather briefly: the descriptions of, and distinctions between, its different forms, are not particularly clear; and on the whole it is a somewhat unsatisfactory chapter, not very helpful clinically. Cicatricial obliteration of the cervix is not a subject upon which there is much to be said, but what little there is, is well given here. The complication of pregnancy with cancer is discussed very fully. The author takes a view which we do not think will commend itself to English accoucheurs, or we might indeed say to any who have studied the subject, viz., that on the principle that in this inevitably fatal disease the life of the child is more valuable than that of the mother, no attempt should be made to remove or destroy the new growth during pregnancy, lest that process should be interrupted. Enough cases, we think, have been published, to show that, in cancer of the cervix sufficiently limited in extent to admit of removal, such removal can be done during pregnancy without much risk of causing abortion, and with much benefit to the patient's health, and therefore to the well-being of the fœtus which she carries. The management of pregnancy and labour when complicated with fibroids is considered at great length and in all its aspects, twenty-five pages being devoted to this subject. The subject is one upon which several excellent monographs have been written by Lambert, Lefour, Chahbazian, Champneys, and others, of which Dr. Charpentier has availed himself. He seems to us to place a little too much confidence in the use of the numerical method in elucidating the subject. The dangers of uterine fibroids, both as to kind and amount, and their proper treatment, depend so largely on the size and situation of the new growth, that to group together a number of cases without reference to these points, seems to us a method not likely to lead to sound conclusions. It is impossible, for instance, to lay down general rules as to the preference of forceps or turning in a class of cases like this. The association of ovarian dropsy with pregnancy is also very elaborately gone into. Here again we cannot but doubt if the author's conclusions will be finally accepted. During pregnancy he recommends tapping (quoting Spencer Wells in support of his view), and during labour he dismisses ovariotomy as impracticable. He does not seem to have read Sir Spencer Wells's later writings on the subject—nor to be aware that ovariotomy has been successfully performed during labour. Other pelvic tumours which may complicate labour are merely mentioned, being all included in the remark, that they exert the same influence on labour as ovarian cysts. Surely this hardly applies alike to hydatid tumours, abscess, hæmatocele, osseous growths, vaginal cysts, rectal disease, &c. References are given, however, to published writings on each class of case, so that the reader who is disappointed with Dr. Charpentier's brevity, can learn where to look for fuller information.

The important subject of rupture of the uterus is handled excellently, the facts relating to it being set forth in a clear and orderly manner, and supplemented by copious references to other sources of information. But in this, as in other chapters, the literary industry of the author seems out of proportion to his power of assimilation, criticism, or original observation. Thus among the causes of rupture of the uterus, we find mentioned (p. 324) "uterine obliquities," followed by the qualifying clause "to which the ancients attached exaggerated importance, although their influence may be real." This would have been appropriate and interesting in a foot note, but why insert, on such slender foundation, "uterine obliquities" among the recognised causes of rupture? Again, we find among the causes of this accident, "exaggerated development of the fundus uteri," and references given to several authors. Feeling by no means satisfied of the existence of this alleged "exaggerated development of the fundus uteri," we looked up the references given, and it appeared to us that the clinical phenomena described, and of which

we have quoted the hypothetical explanation, were just those which Bandl has so ably elucidated by anatomical research. As further on, Dr. Charpentier gives an excellent summary of Bandl's contributions to our knowledge, we are surprised that he did not see that Bandl and his predecessors were describing the same thing. Hæmorrhage before, during and after delivery is then considered, but in a somewhat unequal manner. In placenta prævia the use of the tampon finds more favour with Dr. Charpentier than with most English authors. The directions for the treatment of post-partum hæmorrhage, one of the most trying emergencies that the accoucheur has to meet, are not so definite as we should like to see. The use of perchloride of iron, as recommended by Dr. Barnes, our author would reserve as a last resource. He speaks strongly in favour of compression of the abdominal aorta. A page and a half is devoted to the description of an apparatus by Chassagny for plugging the vagina and uterus, which Dr. Charpentier admits is as yet only in the experimental stage: and which we should not expect to get much further. The injection of hot water, a well-known and most useful provocative of uterine contraction, is mentioned only.

We then come to dystocia dependent upon the fœtus, to which branch of the subject 67 pages are devoted. In the treatment of prolapse of the cord, Dr. Charpentier puts much confidence in the instrumental reposition of the prolapsed part, and figures various instruments for accomplishing this end. Manual reposition he thinks is rarely both possible and advisable; for it is necessary, in his opinion, that the os shall be well dilated before the cord can be pushed up so far that it will not come down again, and in these circumstances it is better to turn. The various diseases of the fœtus which by increasing its bulk obstruct delivery, are very fully described and illustrated. In cases of tardy delivery due to occipito-posterior position of the fœtal head, our author strongly recommends the artificial rotation of the occiput forwards with the forceps. We are entirely in accord with him as to the desirability and practicability of this manœuvre; but we are inclined to think that the safer way of doing it is to introduce the whole hand, and thus seize and rotate the head. Pinard's "eutocic belt," an appliance, which, although perhaps not familiar by name to English accoucheurs, will nevertheless be recognised readily enough when seen, is figured, described, and its advantages and drawbacks discussed, the latter, in Dr. Charpentier's opinion, and in ours, preponderating.

The second of the books into which the work is divided, treats of obstetrical operations. The amount of space that we have already given to our notice of this treatise prevents us from referring otherwise than with brevity to the portions of it which we have yet to speak of. The obstetrical operations are described so fully as to make the section devoted to them one of the best parts of the book. The description of the forceps seems to us largely based on the admirable article on it by Tarnier,[1] an article which no writer on the subject can overlook, or, indeed, help making use of. But Dr. Charpentier's chapter is much more than a mere abstract of Tarnier, for it contains, among other things, a criticism of that obstetrician's "axis traction" forceps, an instrument becoming well known in this country chiefly through the eulogies bestowed upon it by Dr. Robert Barnes. Dr. Charpentier is not one of the warmest admirers of this forceps. He thinks it an excellent instrument when the head is in the pelvic cavity; but when the head is above the brim, he prefers the old form, the "classical forceps," to use his own term. References to statistics are given to illustrate both forceps and turning, comprising upwards of 300,000 cases. The different forms of fillet and of the lever are described, and so is the sericeps of Poullet, an instrument which has not yet found its way into practice, nor so far as we know, into a text book, except the present, and we doubt if its position is likely much to alter. Many different instruments for diminishing the size of the child are also figured.

The final section, dealing with the diseases of the puerperal state, is one of the least satisfactory parts of the work. We have not room to criticise it in detail, we will only say, that while the author admits that many different morbid processes are commonly grouped under the one denomination "puerperal fever," he does not seem to us very successful in setting forth clearly the distinctions between these various forms of disease. The brevity of the account given is in striking contrast to the fulness with which the obstetric instruments are described.

Our examination of the second volume leads us to repeat what we said in reviewing the first. Dr. Charpentier's work is one of the greatest value, one which reflects great credit upon him, and which every obstetric teacher should have. Its value is in the extent of the author's literary researches, the completeness with which all varieties of opinion are given, and the copiousness of reference. But it is not remarkable for originality of view, or philosophic grasp of the subject. The material seems too much for the author's power of digestion. It is a book to be referred to, rather than one to enlighten, explain, and guide. But in its own way it is so excellent, that we heartily thank Dr. Charpentier for producing it.

[1] *Dictionnaire (Nouveau) de Médecine et de Chirurgie Pratiques.*

THE HISTORY OF CHOLERA.[1]

WHATEVER views men may hold as to the etiology and spread of cholera, whether they believe it to be due to a specific and material germ or to other causes, external or internal, telluric, atmospheric, or what not, its epidemic character is recognised by all as the most prominent, if not the sole mark by which it is distinguished from those diarrhœal affections, the exciting causes of which are more easily ascertained or indicated, and which are met with in greater or less degree in every place and at all times. Dr. Macpherson, therefore, resolutely refraining from advancing any theory, or even a definition of cholera, sets himself to the task of searching the medical histories of Europe and Asia for

[1] "Annals of Cholera from the earliest period to the year 1817." By JOHN MACPHERSON, M.D. London: H. K. Lewis, 1884, 8vo, pp. 235.

instances in which an epidemic character is ascribed to any form of gastro-intestinal disease. The nomenclature, medical and popular, of the "fluxes" has at all times been confused, sometimes including dysenteries, catarrhs, &c., under one name, at others needlessly multiplying species; but our author follows the example of the College of Physicians, in recognising, besides the "Asiatic," or cholera pestifera, a cholera simplex, which is more than diarrhœa, and differs from the other only in not being epidemic.

The rice water evacuations, cramps, suppression of urine, cold sweats, and other phenomena of the algid stage, are graphically described by several of the oldest writers, as Aretæus and Cælius Aurelianus; but before the sixteenth century it is only Paulus Ægineta who speaks of an epidemic colic, and its choleraic character is doubtful. Epidemics, marked by stercoraceous vomiting, and bloody stools, or in which rational treatment saved 90 per cent., could not have been the cholera in question; on the other hand, nearly all the symptoms of genuine may be present in cases of bowel disorder, directly due to improper food or drink, and when such insanitary conditions are well nigh universal, the effects, through not strictly epidemic, will be equally wide spread. The dispute as to the treatment, whether by sedatives, purgatives, or diluents, is as old as the name, which, derived from χολὴ or χόλος, denotes any violent disturbance of the digestion, though not necessarily attended by purging, bilious or other, for Hippocrates himself describes a χολέρα ξηρὰ, the cholera sicca of later writers, a colic or ileus.

Although in the sixteenth century bowel complaints, with vomiting, become an important feature in the bills of mortality of London and European cities, the first unequivocal accounts of epidemic cholera are those given in 1643 by the Belgian physician, Van der Heyden, and by his contemporaies, Rivierus and Sydenham. The former remarked that those cases were most fatal which could not be traced to the diet, and the latter, that it differed *toto cœlo* from autumnal diarrhœa. Van Swieten and Willis are equally clear, but during the eighteenth century cholera seems to have produced no very great mortality in Europe, and to have attracted less attention than before or since. But from the first settlement at Goa, early in the sixteenth century, Portuguese, Dutch, French, and English alike were amazed at the virulence of the disease as they saw it in India, and the occurrence of death within a few hours of the attack. At Goa, in 1543, it spared neither man nor beast, and no cause could be assigned for it. During the 17th century we hear of cholera in every part of the East, from Zanzibar to Japan, and so on through the next, though a lull seems to have taken place at the beginning of the present. The outbreak at the fair or pilgrimage of Hurdwar, in 1783, though of short duration, excited much interest at the time, as having been the first appearance of cholera in an epidemic form so far north: but with cholera endemic in Malabar for at least 300 years, and epidemic at one time or another in every province, and knowing that in 1817 it approached Calcutta from Patna Sylhet and Kishnagur, it is incomprehensible how anyone, except the Frenchman who traced the cause of cholera itself to the "cerebral deterioration of the Hindoo consequent on English rule," could seek its origin in the Delta of the Ganges.

Three appendices are attached, one of which on "the analogies of cholera nostras and cholera Indica," is remarkably dispassionate. He shows that the differences are of degree only, not of kind, and that after all that may be urged, it is as impossible to draw a line between them as it is between the mildest and the severest forms of scarlatina or small-pox. Yet the cases are not quite parallel, for while the individual cases of these diseases which make up an epidemic present every possible degree of severity, the worst cases of cholera nostras retain their isolated and sporadic character. Recent events in Egypt have given a fresh interest, scientific, practical, and even political, to this question, and there is no doubt that those who do, and those who do not, believe in the unity or duality, the spontaneous origin and the communicability of cholera, will each and all have ere long to modify their views. The present work not only fills a gap, left alike by Scoutetten and the American report of 1875, but is distinguished from all previous attempts in the same field by the entire absence of any theory as to the etiology or pathology of the disease.

Life History Album; prepared by direction of the Collective Investigation Committee of the British Medical Association. Edited by FRANCIS GALTON, F.R.S.

Record of Family Faculties; by FRANCIS GALTON, F.R.S. London: Macmillan and Co., 1884.

These volumes, by means of which Mr. Galton hopes to obtain data for working out the subject of heredity, are at length in the public's hands, and many no doubt are already engaged in entering their own pecularities and those of their children, as well as their sisters, cousins, and aunts, in the blank forms thus provided. The two books, though their final cause is the same, are worked on a different plan. The "Record of Family Faculties," which will no doubt find the most ready sale, as there is money to be made out of it, is intended for statistics of one's immediate ancestry. The scheme has been well thought out, and, apart from the prospect of a prize, the mere filling in of the records will no doubt afford interest and amusement to many hundreds of competitors. The only fear is, that those who are best fitted to send in accurate and trustworthy returns will be just those who have the least time to make those researches which will be necessary for success. On the project involved in the "Life History Album," we have commented sufficiently in another column. It will be enough to say here, that the forms are admirably adapted for the purpose in view.

Elements of Pharmacy, Materia Medica and Therapeutics; by WILLIAM WHITLA, M.D. (Q.U I.) Second Edition. Renshaw, 1884, pp. 602.—Originally published little more than two years ago, and already needing a second edition, this book requires little praise to commend it. Dr. Whitla has divided his subject into three portions, as indicated on the title page, and has not attempted to arrange drugs otherwise than alphabetically. Questionable as this arrangement may appear, the author states that friendly criticisms have convinced him of the propriety of not changing it. A very valuable section is devoted to non-officinal remedies, and the care with which this portion has been compiled may be inferred from its containing notices of kairin, convallaria majalis, tonga and sodium nitrite. As it stands, this work should form a convenient book of reference for busy practitioners who wish in a moment to turn to the materia medica, therapeutics, or chemical reactions of any drug. It also appears to be admirably adapted to the requirements of the College of Physicians, the sectional arrangement enabling students to study only those portions

which they are able to grasp in their first year. The value of the work for examination purposes would be greatly increased by the addition of a few pages grouping medicinal plants under their natural orders. Industrious students might form this classification for themselves, but only with infinite work.

The Surgical Treatment of Bladder Tumours; by Messrs. Whitehead and Pallard. J. and A. Churchill and J. E. Cornish.—This pamphlet is a reprint of some papers, which appeared in our contemporary, the *Lancet*, at the latter part of last year. As they have, doubtless, been read by a large section of those interested in such work, it is not necessary for us to do more than draw attention to the fact, that the papers are now issued in a separate and collected form. The authors fairly state their subject, and summarise, in tabular form, all the hitherto recorded cases in which membranous urethrotomy has been practised, either for tumour in the bladder, or as an exploratory operation in cases where tumour was suspected.

The Roller Bandage; by Dr. Hopkins. Lippincott, Philadelphia.—The author's plan appears to be the teaching of the art of bandaging by numerous illustrations rather than by elaborate description. Each bandage is illustrated in process of being applied rather than as a completed operation, and the student is thus able to follow the various turns and twists which are necessary to make it fit appropriately and look nice when finished. Of course the illustrations are supplemented by some text; but we gather from the 73 illustrations scattered throughout the book that, contrary to what generally obtains, the text is subsidiary to them. We can recommend the work as very simple and very practical.

A Compend of Surgery; by Dr. Orville Horwitz. Henry Plimpton.—This little book is No. 9 of the Test Series (to some of which we referred in our issue of November 10, 1883). The present volume is rather better than some of the others in this series. It is illustrated with woodcuts, some of which are very familar, and have done excellent service many times over.

ABSTRACTS AND EXTRACTS.

Migraine.—Dr. William A. Hammond, in a suggestive article on this disease, published in the *New York Med. Jour.* (Nov. 17th), says that, until a few years since, the therapeutics of migraine "consisted of a mass of empirical formulæ, constructed upon the shot-gun principle, and directed to the stomach, the nerves, the liver, &c., according to the particular views held by the concoctor." He maintains, however, that through the labours of recent investigators, our views in regard to the essential nature of the malady, and the methods of treatment to be deduced therefrom, are probably as exact as they are in any other disease, and likely to be followed by as beneficial results. He recognises two distinct types of migraine:—1. The angio-spastic, spasmodic, or sympathico-tonic form, due to vascular spasm, producing local encephalic anæmia. It is characterised by pain, nausea, and vomiting, noises in the ear, circles or flashes of light in the eye, mental and physical prostration—and especially by certain oculo-pupillary and vaso-motor disturbances, which are diagnostic of the type, and usually easy of recognition. Thus, during the paroxysm, the pupil on the affected side is dilated, while the eye appears deeper sunk in the socket than is its fellow. The face and ear on the painful side are pale and cold to the touch; the temporal artery contracted and cord-like; and a thermometer with its bulb in the external auditory canal registers a temperature about 0·5° F. below that of the other side. Ophthalmoscopic examination shows that the choroid is paler, and the retinal vessels smaller than normal. Whatever tends to diminish the flow of blood to the painful region—*e.g.*, compression of the carotid on the affected side—increases the intensity of the symptoms; while the pain, &c., are lessened by anything which increases the quantity of intra-cranial blood, as by pressure on the opposite carotid, causing a diversion of blood through the contracted artery; a certain amount of reaction attends the passing off of the paroxysm. As regards treatment, the indications are to relax vascular spasm, and to augment the volume of intra-cranial blood. To this end, *galvanism* is of great service—one pole being applied over the cervical sympathetic, and the other over the solar plexus, and a current from about fifteen cells being allowed to pass for two or three minutes. Still better is the administration of a quarter of a grain of morphia hypodermically, followed by a drop of a one-per-cent. solution of nitro-glycerin every fifteen minutes in pill or on sugar. Specific ætiological complications require special modifications of this treatment; thus, if the migraine own a malarial origin, a large dose (half a drachm is not too much) of sulphate of quinine should be given instead of the morphia. During the intervals, the bromides should be administered persistently for months; and, during the same period, glonoin (one drop of the one-per-cent. solution three times a day). 2. In the paralytic form the coats of the arteries are relaxed. During a paroxysm the pupil is contracted as is the opening of the eyelids on the affected side; the ear and side of the face are redder and hotter than usual; a thermometer inserted in the meatus indicates a temperature increased by from 0·2° to 0·5° F. over that of the sound side. The temporal artery is enlarged and tortuous, and pulsates with abnormal vigour. The *fundus oculi* appears of a bright scarlet colour. Compression of the carotid on the affected side lessens the pain; and whatever tends to increase the amount of intra-cranial blood intensifies all the symptoms. In this form, galvanism, applied as previously mentioned, is often equally efficacious in cutting short a paroxysm. Cold to the nape of the neck is useful; and compression of the carotid artery on the affected side sometimes acts like a charm. Thirty or forty grains of guarana, or ten grains of caffeine, or even strong tea or coffee, will often cut short a seizure; but better still is a large dose—a hundred grains—of sodic bromide, this rarely fails to abort a paroxysm; "the bromides not only relax vaso-motor spasm, but give tone to vessels whose coats are relaxed." Treatment during the intervals should consist of the bromides, ergot, and strychnine. Dr. Hammond mentions that these two conditions, described above, sometimes alternate—one paroxysm being of the spasmodic variety, and another presenting all the phenomena of the paralytic type. Occasionally both may exist at the same time on the opposite sides. At other times the oculo-pupillary and vaso-motor symptoms may be absent, the pain alone being present; in such cases, however, indications for the therapeutics can often be obtained by observing the effect (as regards increase or diminution of the pain, &c.) of making pressure on the carotid artery of the affected side. It is pointed out that, in both forms of the disease, attention must be given to securing a satisfactory condition of the stomach and bowels. Attacks of either kind are sometimes induced by the presence of undigested food—in which case an emetic or a purgative aborts the paroxysm at once.

Sciatic Neuritis in Phthisis.—An account is given in the *Gazette des Hôpitaux* (Nov. 16), of a case of this description which came under Dr. Landouzy's care at the Charité. A woman, 33 years of age, but apparently much older, applied on account of an affection of the chest, and on examination, manifested all the signs of extensive tubercular infiltration of the left lung. There was also remarkable atrophy of the right leg, and although the woman did not apply with respect to this, she admitted that for the last 18 months she had constantly suffered severe pain in this limb, whether she was using it or not, and at night as well as by day. The seat of pain was referred to the sciatic nerve at its exit, and along the course of its trunk and principal branches. This peculiar course and continuity of the pain were pointed out by the late Professor Lasègue as the means of diagnosing between sciatic neuritis and neuralgia, and Dr. Landouzy did not hesitate to attribute the present case to the former affection, especially as it was also accompanied by marked atrophy of the limb. As to the relation of the neuritis to the tubercular infec-

tion, it is to be observed that the patient, who had no family or personal history of phthisis, had cohabited with two men in succession who were the subjects of this disease; but she did not complain of her health until 18 months before her admission, when she became the subject of peritonitis, and afterwards of fistula in ano, for which she underwent operation. It was during this period also that the painful affection of the leg commenced, and that she was seized with cough and hæmoptysis. Dr. Landouzy does not hesitate to regard the neuritis as one of the localisations of tubercle, of which other examples are on record. Professor Peter, for example, in his *Clinique Médicale*, has shown by several examples that disturbances in innervation of the highest importance may be produced in phthisis, and that they are associated with its most serious forms, or appear at the moment of definitive and hopeless aggravation of the tubercular disease—becoming an indication of the extreme gravity of the disease and of the approaching death of the patient. He refers to two such cases of sciatic neuralgia, or rather neuritis; at his instigation, M. Friot produced, in 1879, a thesis in which this point in the history of tuberculosis was examined. Among 137 cases of phthisis admitted into Professor Peter's wards in 1878, M. Friot met with four instances of the occurrence of sciatica in the course of phthisis, which, joined to Professor Peter's two cases, and five others reported elsewhere, form the material for his conclusions. In Professor Peter's two cases, and in three of those related by M. Friot, as well as in the one which forms the subject of his paper, the sciatica closely coincided with the commencement of the pulmonary tuberculosis. His conclusion is that sciatic neuritis depends upon a special anatomical lesion, such as tuberculosis, influencing the nervous substance or its coverings and acting upon neighbouring nerves. Two of his cases tend to prove that in tubercular sciatica there is always a changed condition of the spinal cord or its membranes, a condition of a variable character, but capable of producing secondarily a peripheral neuritis. Summing up the results of M. Friot's eleven observations, it seems that this neuritis may commence the series of affections associated with phthisis, or burst out during the course of the disease. The pains in place of being intermittent as in neuralgia are constant and very obstinate; and their appearance should give rise to the suspicion of tubercular change either in the cord or its membranes, or in the spinal column. They tend to aggravate the disease, and generally precede only by a short time the fatal termination. While in sciatic neuralgia we may obtain a cure by means of narcotics and antispasmodics, antiphlogistics furnish the only means of relieving the pains of neuritis, while a complete cure is in all cases unattainable.

The Uterine Mucous Membrane during Menstruation.—A recent number of the *Zeitschrift für Geburtshülfe und Gynäkologie* contains a paper on this subject by Dr. Theodor Wyder, of Zurich. He commences with a criticism of the observations of others on the point, and takes exception to most of them on the ground that sufficient care has not been taken to discriminate the effects of disease and of post mortem alterations from physiological changes. He admits some few former descriptions as valid, and has made observations on nine women himself. His own were made in the following manner. He chose women in health and menstruating regularly. During menstruation a speculum, not oiled, was passed, and the blood and mucus oozing from the cervical canal were collected with a glass rod or a syringe, neither instrument being oiled, and care being taken not to let it enter the cervical canal lest any cervical structures should be accidentally detached. The blood and mucus thus procured were examined microscopically. He comes to the following conclusions:—1. During menstruation a part of the superficial layer of the mucous membrane is destroyed, while the rest persists. This removal of the superficial layer of mucous membrane takes place to a different degree in different cases, sometimes being complete, sometimes "minimal." The separated layer in part retains its structure, in part is broken up into detritus, in some cases small bits of mucous membrane, in structure like the membranes of dysmenorrhœa membranacea, but causing no pain on account of their smallness, being found in the menstrual discharge. 2. The separation is a consequence of the menstrual hæmorrhage, and not of primary fatty degeneration. This latter is rather a consequence of the detachment and breaking up of the mucous membrane effected by the bleeding. 3. The superficial and middle layers of the remaining mucosa are composed of small cells, and have no resemblance to the decidua of pregnancy; while in the deeper layers there is a cellular hyperplasia of the interglandular tissue plainly intended to reproduce the tissue cast off during menstruation. 4. The regeneration of superficial epithelium takes place both from the glandular epithelium, and from the larger or smaller islets of superficial epithelium that may remain.

Water in the Dietary of Young Children.—In a communication to the *New York Medical Journal* (September 29), Dr. Remsen, of the Nursery and Child's Hospital, calls attention to the general ignorance which prevails as to the necessity of furnishing infants with a sufficient quantity of water, especially in hot weather, and whether they are brought up at the breast, or artificially. For want of this, the fluid portion of any food introduced into the stomach is quickly taken up, leaving the solids too thick to be easily digested. They ferment and produce indigestion and colic, together with diarrhœa. As a consequence of the thickened state of the blood thus produced, excretion of sweat is arrested, and a state of collapse and hyperpyrexia is developed. In warm, dry weather, babies will drink cool water every hour, or oftener, if it is, as it should be, offered them. The earliest sign of the water in the system being below its normal standard is a slightly depressed condition of the anterior fontanelle. This may be present in children apparently in perfect health, yet in whom a slight increase of temperature or the deprivation of the breast for a few hours, may give rise to sudden hyperpyrexia. Attention is, however, usually first aroused by the fretfulness of the child, a moderate rise of temperature and pulse, a hot, dry skin, and a constant desire to suck. If a free supply of water be given, and nursing restricted in frequency, these symptoms will often disappear completely and quickly, but if not, collapse will soon come on. The temperature ranges from 105° to 106° F., or higher; the pulse is small and thready, numbering from 180 to 200; the skin of the body is painfully hot, while the extremities are cold; the features are pinched and sunken, with the eyes half-closed and the pupils contracted; the fontanelle is depressed, the hands are tightly shut, the respiration is hurried and irregular, and consciousness seems abolished. A child in this state will swallow water with greediness and the utmost pleasure. The treatment adopted at the Nursery has been wrapping the patient in a wet sheet, applying cold to the head, and giving as much water as can be swallowed. The results have been very satisfactory, the child becoming quiet, and even going to sleep, while all the threatening symptoms rapidly subside. "The attention given to this point as a prophylactic measure has been followed by a diminished rate of mortality, and a marked reduction in the number of gastric and intestinal complaints. If more care was taken to give children a proper amount of water, and restricting their hours of sucking or feeding, the mortality due to hot weather would decrease, and less would be heard about the troubles of teething."

Prof. Paul Bert's Method of Administering Chloroform.—The *Gazette des Hôpitaux* (1884, No. 1), furnishes an account of the first trials which have been made of this method on the human subjects, after 300 experiments had been performed on dogs with satisfactory results. M. Dubois, the laboratory assistant of Prof. Bert, described to a large assemblage at M. Péan's Clinique, at the St. Louis, the mechanism of the gasometer made use of, and stated that 8 cubic centimetres of chloroform to 100 litres of atmospheric air had been, by experiment, found to be a satisfactory combination. In the six cases then operated upon, anæsthesia was induced without preliminary local irritation of the mucous membrane, in a few minutes, the pulse and respiration continuing regular during the anæsthesia.

M. Péan observed, after the operations were concluded, "that there was every reason to hope that future trials would confirm these results, and the exact dosage of anæsthetics will certainly prove one of the glories of French physiology."

Nephritis as a Sequela of Varicella.—Professor E. Henoch, in the *Berlin. Klinische Wochenschr.*, No. 2, relates four cases of nephritis which followed after, and apparently as the result of, attacks of chicken-pox. The attacks of chicken-pox were accompanied by moderate fever, and occurred in children whose ages were 2 years, 4 years, 5 years, and 10 years. The nephritis supervened from 8 to 10 days after the commencement of the onset of the chicken-pox, and was accompanied by albuminuria, pallor, and œdema of the face, hands, and feet. The urine also contained casts, epithelial cells, and blood corpuscles. In three of the cases, recovery took place in the course of a few weeks; the treatment consisted of vapour-baths, acetate of potash or "Bilin" water. In the 4th case, death took place suddenly on the 17th day from the commencement of the nephritis. At the post-mortem there was found moderate hypertrophy and dilatation of the left ventricle, normal valves, œdema of the lungs, and acute parenchymatous nephritis. Henoch remarks that he has failed to find similar cases recorded, and points to the necessity of retaining the patient in bed, and examining the urine, especially during the second week of the attack.

Congenital Absence of a Portion of the Ileum.—In the October number of the *Medicinisch-Chirurgisches Correspondenz-Blatt*, a new journal published at Buffalo, N.Y., for the benefit of German doctors practising in the United States, an interesting case of congenital occlusion of intestine is related, in which an important ethical question is raised. The child, a well-formed female, suffered in about six hours from its birth from fæcal vomiting, purgative remedies being rejected in like manner. No defect could be detected in the anus or rectum. An operation for the establishment of an artificial anus was proposed, but refused by the parents. After death, the whole of the large intestine and the lower ten inches of the ileum were found empty, shrunken, and contracted; above this the small intestine to the duodenum was immensely distended. An interval of about three-quarters of an inch was found in which the continuity of the intestinal tube was interrupted, both upper and lower segments of intestine ending in a *cul-de-sac*. Under such circumstances, an artificial anus must of necessity be permanent. Dr. Krombeia, who communicates the case, is clearly of opinion that, with such a prospect, the duty of the doctor is "to leave the case to Nature."

The Hypophosphites without Syrup.—Dr. G. S. Gerhard recommends the following formula:—℞ Calcii Hypophosph., Potassii Hypophosph., Sodii Hypophosph., āā gr. j; Quiniæ Hypophosph., Mangan. Hypophosph., aā gr. ¼; Ferri Hypophosph., gr. ½; Strychniæ Hypophosph., gr. $\frac{1}{120}$; Glycerini, ♏ iij; Liq. Acid Hyposulph., ♏ ij; Aq., ad ℥.ʒ j. The addition of a definite amount of hyposulphurous acid prevents the precipitation of at least two of the salts (those of iron and manganese). The solution is clear, slightly fluorescent, and pleasantly acid. This formula is certainly an improvement on the ordinary syrups, the excess of sugar in which often decreases the appetite and deranges digestion. Two minims of Acid. Phosphoric. dilut. B.P., if substituted for the hyposulphurous acid in the above formula, appear to be equally efficacious in preventing precipitation. If the iron and manganese be omitted, a few drops of dilute Hydrobromic Acid serve to maintain the other ingredients in clear and permanent solution. (*Phil. Med. Times, Nov.* 3, 1883).

Coxalgic Mimesis.—Dr. J. L. Bauer corroborates the statement first made by Dr. Gibney, of New York, concerning the frequent similarity between the symptoms exhibited in cases of morbus coxæ, and in perinephritis and pyonephrosis. The coxalgic symptoms—joint pain, with flexion and abduction, or adduction of the limb—appear when the pus "penetrates the sheath of the psoas muscle, and, securing no outlet, occasions a constant pressure in every direction upon the neighbouring nerves and tissues." Differential diagnosis may be very difficult in the early stage, and demands a careful examination of the lumbar region, whether there be any history of previous urinary trouble or not. In the stage of adduction and flexion, the production of anæsthesia is probably the only means of resolving doubt, unless the abscess have already opened; in the one case, these symptoms completely disappear, while, *in coxalgia, the muscular contractions and pain are relieved neither by anæsthesia nor by the creation of fistulous tracts.* In coxalgia, too, the existence of articular effusion or of a defined roughness of the articular cartilages may be discovered. (*New York Medical Record, Dec.* 8, 1883).

Antiseptic Pomade.—Dr. Lucas Championnière (*Union Med.*, Jan. 1878) recommends the following formula:—Powdered boracic acid 6 parts, vaseline 30 parts. The acid is to be incorporated after it has been passed through a sieve, with the vaseline, and without dissolving it in alcohol or glycerine, which renders the pomade irritating. If it is wished to scent it, half a part of balsam of Peru may be added. This pomade will keep for an indefinite length of time. It may be spread on linen or salicylated wadding, and is employed with success in fetid eczema, fetid transpiration of the feet, and in the intertrigo and erythema of new-born infants.

The Artificial Cultivation of the Vaccine Virus.—The *Boston Med. and Surg. Jour.*, Dec. 20, 1883, prints a communication from St. Petersburg, giving a *resumé* of the communication recently made by Dr. Qvist to the Medical Society of Finland, on this subject. He states that the vaccine bacterium is a veritable *aërobium*, and in the lymph spaces of the skin it finds sufficient air containing the carbon dioxide requisite for its normal development. For the culture-fluid, he prefers to use egg-albumen mixed with glycerin; the hygroscopic qualities of the glycerin obviate that partial desiccation to which egg-albumen alone is liable when exposed to the air, and which prevents the successful cultivation of the bacteria. Moreover, a large proportion of glycerin, while favourable to the propagation of the vaccine germs, destroys the ordinary mould fungi, whose presence would otherwise interfere with the successful growth of the former; the vaccine bacteria, again, prefer an alkaline vehicle. Dr. Qvist gives four formulæ of cultivation fluids, which consist essentially of bovine blood-serum, or of egg-albumen, with glycerine, water, and a small per-centage of calcic carbonate. The culture-vehicle itself is efficiently sterilized by subjecting it to a constant temperature of 60° C. for one and a half hours continuously for three successive days. A favourable temperature for cultivation is found to be the usual summer heat, or that of a warmed house in winter—about 19° C. to 20° C. As "vaccine seed" he has used ripe lymph imbibed by a piece of dry sterilized sponge, which is transferred to the culture-fluid in a watch glass; or, preferably, he removes a piece of epidermis from a true vaccine pustule on the eighth or tenth day, taking care that no blood-serum is attached to it, cleanses it by washing, and, after two days' careful drying, places it in the culture-fluid. The watch glass should be placed on a table or shelf, exposed to moist air, and covered by a clean tumbler. If a concentrated virus is required, a test-tube is preferable to the watch glass, and it should be closed with a cork coated with sterilized paraffin, leaving a minute air-hole on the side of the cork. In the course of a day or two the culture-medium becomes turbid, and gradually it assumes a yellow or straw colour. In seven or ten days, scales form on the upper surface of the liquid, and a fine powder falls to the bottom of the glass. This powder, which is also attached to the scales, contains the bacteria. Vaccine lymph thus artificially prepared can be preserved in capillary glass tubes, and used as required. Dr. Qvist is alleged to have proved by inoculation in several instances that his artificially prepared lymph produced pure vaccine vesicles.

Menstruation after Removal of the Ovaries.—In a paper read at the meeting of the American Gynæcological Society (*Philadelphia Medical News*, September 29), Dr. Campbell, of Augusta, asserted that menstruation often continued after removal of the ovaries, and attributed this to the fact that the function is influenced from the lower portion of the spinal cord. Dr. Goodell, of Philadelphia, speaking from his large experience, maintained that such menstruation is very rare, although in all his removals of the ovaries he had met with a spurious menstruation, appearing about five days after the operation, and which he attributed to the irritation of the nerves included in the ligatures. Two cases only of menstruation have occurred to him: in one, the bleeding was not in fact menstrual, but due to a sarcomatous tumour of the uterus. In the other, menstruation has continued regularly since the operation. This he considers may be due either to some abnormally placed ovarian tissue that had been left behind, or to sufficient time not having elapsed to break up the habit of menstruation. Dr. Emmett, of New York, referred to a case in which the patient, when last heard of, had menstruated thirteen times, the discharge, which, prior to the operation had been excessive, having become natural. Dr. Gaillard Thomas, of New York, said that he had removed both ovaries between fifty and sixty times, and he believes that the exceptional cases of apparent menstruation after the operation, are really examples of metrostaxis, the uterus, having been in the habit of menstruating, continuing awhile the function. The bleeding gradually diminishes, and finally disappears. There are numerous cases on record in which impregnation has followed upon removal of both ovaries, and he believes that these were dependent upon the presence of a third ovary. Dr. Byford, of Chicago, observed that the frequency of this occurrence depends much upon what is regarded as menstruation. If it occurs only when ovulation takes place, it is very rare, and can only be due to some of the ovarian structure being left behind. A mere discharge of blood may occur in many cases; and almost invariably, if the periods of recurrence be noted, it will be found that the discharge is a mere metrorrhagia and not menstruation.

Congenital Absence of Left Kidney.—Two cases have recently been reported in America, in each of which post-mortem examination revealed the existence of but a single kidney. In both it was the left organ that was wanting. The patients were adults—a woman, æt. 45, and a man, æt. 65; in the former the left supra-renal capsule, somewhat larger than normal, occupied its usual position; the right kidney was very small, about the size and shape of a hen's egg, and death was probably to be accounted for mainly by its diseased condition (interstitial nephritis). The man died of cancer of the stomach; his single (right) kidney was very large, but healthy.—*Boston Med. and Surg. Jour.*, Dec. 20, 1883.

Actinomycosis in American Cattle.—This malady was first recognised, six years ago, by Böllinger, of Munich, who described it as a parasitic disease, due to the presence of a rapidly growing fungus. Since then it has been discovered in man and in the hog. Quite recently Dr. Belfield has recognised it in the cattle disease generally known as "swell-head," and called by veterinarians cancer, sarcoma, &c., which he was asked to investigate by the Commissioner of Health of Chicago. Its source is believed to be the grain on which the animal is fed. It generally first attacks the jaws, and gains access to the deeper structures through carious or defective teeth: spreading into the tissues of the head, it produces tumefaction, suppuration, and finally, if unchecked, even pyæmia and death. By means of the blood it may be transferred to other parts of the body—and this happens especially in man, upon whom the parasite acts most virulently. The flesh of animals dying of actinomycosis is not of first quality, but does not appear to be absolutely injurious; thorough cooking, at any rate, destroys the parasite. (*New York Medical Record, Dec.* 8, 1883).

Case of Poisoning by Tartar Emetic. — Dr. J. S. Carpenter relates in the *New York Med. Record* for October 13, the case of a man, 21 years of age, who was employed in the Dispensary Department of the Episcopal Hospital, at Philadelphia, and who took in mistake a glass of solution of tartar emetic, containing, it was afterwards calculated, 170 grains. No ill effects occurred for a quarter of an hour, when he was seized with intense vomiting, which recurred many times, accompanied by violent pain in the œsophagus and at the epigastrium. When put to bed in the hospital, he was in a state of prostration almost amounting to collapse, and suffered from distressing pain. Tannic acid solution was administered abundantly as an antidote, followed by albuminous drinks, and tincture of opium was given to allay the burning pain. The temperature was only 95° F. and a strong intermittent pulse could hardly be perceived. Small and frequent doses of spir. frumenti and liq. calcis were given and external stimulation, by means of hot-water cans and vigorous friction, was kept up; but it was only after 3 hours of unremitting efforts that reaction was established, the temperature rising to 99·5°, and the pulse improving. A "rice-water" evacuation, streaked with blood, and accompanied by severe cramp in his legs for several hours after admission, was the only evidence of intestinal irritation. The deodorised tincture of opium (of which 220 drops were taken within 2 hours), together with morphia hypodermic injection, greatly relieved the pains of the abdomen. The distressing thirst was met with a grateful drink, formed of an egg and milk mixture with ice. After 3 or 4 days' rest in bed, the patient was discharged, cured. The urine, which according to some authorities is increased, was in this case very scanty, so as to be almost suppressed. There was no disturbance of the respiratory or sensory functions.

REPORTS OF SOCIETIES.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

Tuesday, January 22nd, 1884.

John Marshall, F.R.S., President, in the Chair.

On taking the chair at the ordinary meeting of the Society, on Tuesday last, the president referred in feeling terms to the great loss which the Society had sustained since their last meeting, in the death of Mr. B. R. Wheatley, their resident librarian. It would be difficult, he said, if not impossible, to replace such a man. He should reserve further remarks on Mr. Wheatley until the annual meeting, when he hoped to be able to pay a tribute to his memory such as his services to the Society entitled him to.

Three communications were then read, of which the following are extracts:—

On the Mechanism which regulates the Arterial Blood-pressure in Health and Disease.

By Charles L. Roy, M.D., of the Brown Institution. The subjects especially dealt with in this address were—

1st. Effect on the blood-pressure of closure of one or more of the larger branches of the aorta, and comparison of this with the effect produced by the injection into the blood-vessels of a considerable quantity of defibrinated blood, or of a neutral fluid such as weak solution of salt.

2nd. The mechanisms which take part in regulating the blood-pressure under the above conditions.

(*a*) The heart, and the methods of investigating its action and the work done by it.

(*b*) The larger and smaller arteries. The elasticity of their walls, and the methods of investigating it, with its influence on the form of the pulse wave and the practical conclusions which may be drawn from the latter regarding the condition of the arterial circulation.

(*c*) The peripheral circulation and the methods of investigating it in the kidney, muscle, skin, and spleen. The

mechanism of the regulation of the peripheral circulation. Method of investigating the capillary circulation.

3rd. The changes in the above which accompany some of the principal types of diseased processes affecting the circulation.

A case of Spina Bifida.

Mr. WHITEHEAD (Manchester) shewed a woman who had been under his treatment in the Royal Infirmary, on account of spina bifida.—The following were the principal points in the case:—Although the woman had a spina bifida, in the lowest part of the spinal column, there appeared to be no paralysis, and she had gone on well for 21 years, during which the tumour had remained stationary. After an unfortunate marriage, the tumour began to enlarge, at first slowly, and subsequently more rapidly. When about 28 years of age, dangerous nervous symptoms began to manifest themselves, and then she applied for advice at the Royal Infirmary. With a view to combat these symptoms, the tumour was tapped, and large quantities of clear cerebro-spinal fluid were withdrawn: but the nerve symptoms only became aggravated. It was then determined to apply powerful counter-irritation to the tumour in the shape of the actual cautery, this being drawn cross-ways over the tumour. Very shortly afterwards, the fluid in the sac became puriform, and Mr. Whitehead decided to lay it freely open. Layers of antiseptic gauze were kept applied, and a complete cure finally resulted.

THE PRESIDENT thought it an interesting case, but that it differed from ordinary spina bifida as seen in infancy, in not having so extensive a communication with the cord.

Mr. WHITEHEAD, in answer to Mr. Parker, said the opening into the spinal canal at the time he laid open the sac was closed by granulation tissue.

Preliminary Communication on the Existence of Sensory Nerves in Nerve Trunks, true "Nervi Nervorum."

Mr. VICTOR HORSLEY contributed a paper with this title and showed a large number of microscopical sections in illustration of it. The following is an abstract of the paper:—Although a fertile source of theory for some time, true sensory nerves have not been described hitherto as supplying nerve trunks. Both Sappey ('Traité d'Anatomie descriptive,' p. 223, 1872) and Krause ('Handbuch der Menschlichen Anatomie,' 1882, evidently following Sappey's description) mention fine nerve branches forming a vasomotor plexus around the vessels of the epineurium. In addition to these, which can be demonstrated with ease, there exist also (in man) true sensory nerves concealed by the fat cells of the epineurium and terminating by end bulbs on the perineurium. These alone should be termed "nervi nervorum," those above-mentioned being properly "nervi vasorum." They appear to arise occasionally from the primary bundles of nerve fibres, but also (and perhaps more frequently) from the cutaneous (?) branches given off by the former. Their direction is first at right angles to the primary bundles and then parallel, running as single medullated fibres of medium size, in the connective tissue of the epineurium, and terminating in end bulbs very similar to those found in the conjunctiva, &c., and which consist of a connective-tissue capsule, containing a protoplasmic core at the base, and two nucleated protoplasmic corpuscles at the extremity, close by which the axis cylinder can be traced, but without appearing to end in them. The localisation of pain in neuralgia, referred to by Mr. Marshall in the Bradshawe Lecture, 1882, is thus accounted for, and an additional aid to "muscular sense" suggested.

THE PRESIDENT had taken great interest in the subject; he had long believed that nervi nervorum existed, and had suggested to Mr. Horsley the desirability of working out the problem. He was grateful that Mr. Horsley had so ably carried out the research, and pleased with the successful result of his work.

Dr. HOGGAN thought that the preparations exhibited hardly bore out Mr. Horsley's conclusions. The small nerve fibres passing from the trunks, he thought, were merely interweaving branches of fasciculi. In teased nerves medullated fibres were often found running with vessels, but they did not go to supply the vessels. As regarded the end bulbs, he thought they were ganglia: and as regarded the presence of Pacinian bodies on the extremities of the ulnar nerve, he thought this was only what was usually taught.

Mr. HORSLEY, in reply, said the single nerve fibres were provided with a special sheath: they were very wavy and lay over the fasciculi, the interlacing bundles of which were straight in outline. He had not stated that medullated nerve fibres went to the vessels, but the contrary: moreover, his preparations were not teased ones. The appearance of corpuscles, he said, was fallacious, the interior being a twisted core, as seen in the end bulbs; they did not in the least resemble the ganglion cells found in the frog, &c. As to the Pacinian corpuscles, those he had described were found on the ulnar nerve above the inner condyle of the humerus.

The Society then adjourned.

GENERAL CORRESPONDENCE.

CONSULTANTS AND GENERAL PRACTITIONERS.

[To the Editor of the Medical Times.]

SIR,—Allow me to thank "Z." for his courteous reply to my former letter, which however, has not made the subject much more clear to me. I do not myself regard with the aversion that he does "the dabbling by consultants in general practice," but I do challenge the right of those who do so, *sub rosâ*, to pretend to a higher status, than those who *openly* do the very same thing. Will "Z." kindly oblige me by stating clearly and distinctly the line of demarcation between the consultant and general practitioner, and show that it is *not* one habitually crossed by the former? I shall be genuinely grateful to him if he can show me, that what appears to me a chaos (not unmixed with a little humbug —, pardon the word) is a rational, well organized, and *universally observed* system. Touching "Z.'s" reasons for hospital physicians being so far superior to others, I regret that I can only partially agree with him. In other arts than ours—and we must never forget that medicine is an art as well as a science—the teacher is frequently far inferior to those who are not teachers. Our greatest orators have not usually taught rhetoric, our greatest musicians been professors of music, nor our greatest artists drawing masters. "Z." talks of "men more remarkable for knowledge of the world than for knowledge of pathology." But I maintain that a good physician should be both, and that where hospital men are often so deficient is in the former qualification. An experience gained *solely* from the class of patients who form the bulk of hospital cases will often prove at fault, when applied to a class whose whole habits and environment are totally different. Scientific pathology will not *alone* enable the physician to guide aright the crotchetty and bilious old Indian, with peculiar views upon diet, and mode of life generally, nor those suffering from the complaints of modern society. A word to "Medicus." He apparently confounds the man who has scraped through the easiest available curriculum, and qualification, with the man who has spent five, six, or more years, and taken the highest degree obtainable, at a University—and who, after filling all the hospital posts below hon. assistant physician or surgeon, has subsequently cultivated private practice instead of only hospital. Now I maintain that the gap is infinitely greater between these two men than between the latter and the ordinary hospital physician. I do not think that a man should attempt the Herculean task of cultivating the progress of every branch, all round, but should with-

draw from those that he feels are not his best line, and cultivate only what he feels is so. I myself have long since abandoned surgery--though a school prizeman--merely because I found it impossible to conscientiously continue my study of it is as well as of medicine, which latter I preferred.

But because I do not hold a hospital appointment, and have not inflicted a compilation of platitudes upon my brethren, am I to consider myself in the same professional category with the gentleman round the corner, with his red lamp, and bottles of physic in the window? I hope that I am not doing "Medicus" an injustice when I say that, judging from the tone of his letter, he may possibly say "yes" to the above. I have certainly met some who would, but am consoled by the fact, that so many of my patients who know the world pretty well, think differently. "Medicus's" observation concerning "consultants, who have prepared themselves for special lines of practice, by prolonged study of certain departments of disease," reminds me of a case which came to me after treatment by an eminent consultant, who had quite correctly diagnosed a deposit of tubercle at the apices of both lungs, and was treating him accordingly, but who unfortunately overlooked the fact that the man was suffering from renal cirrhosis, of which he died long before the lung mischief had developed to any serious extent.

And specialism has this danger for humanity, that the body is not a mechanical thing, like a gun, in which the stock maker, the lock maker, and the barrel maker can work absolutely irrespective of the others, but is a complex cosmos, with its component parts and forces so correlated as to necessitate a broad view being taken of even an apparently localized disorder.

I am, Sir, &c.,

M.D.

MEDICAL NEWS.

Poor Law Appointments in Ireland.—A singular dispute has arisen between the guardians of the Listowel Union and the Local Government Board. The guardians recently appointed Dr. Dillon to be medical officer, but the vice-chairman objected to the appointment on several grounds, but especially because, as he alleged, Dr. Dillon had given a sum of money to his predecessor to create a vacancy by resigning. The Local Government Board, after receiving Dr. Dillon's explanation, expressed their strong disapproval of all such transactions, and refused to sanction the appointment. The guardians were required to proceed with a new election, and, after advertising for candidates, the new election was held, and Dr. Dillon was again elected by a large majority, some of the guardians who supported him observing that they felt sure the Local Government Board would sanction the appointment this time. The ultimate action of the Local Government Board is awaited with considerable interest, as the practice is understood to be frequently resorted to, not only in the Poor Law Medical Relief, but in other public departments.

A Year's Mortality in Edinburgh.—In the course of the past year 4,275 deaths were recorded in Edinburgh, being equal to a rate of 18·22 per 1,000. The average rate for the previous five years was 19·69. No fewer than 446 deaths were registered as having been due to preventible causes. There was a marked diminution in the number of fatal cases of typhoid fever, the mortality amounting to 40, as compared with 71 in 1882. On the other hand, there was a considerably increased mortality from measles—a disease which has been epidemic in the city for some months. The deaths during the year numbered 138, as compared against 87 in 1882. With regard to the 5,411 notifications by practitioners as to the outbreak of infectious diseases in the city, those concerning scarlatina numbered 1,817, while notice was given of nearly 3,000 cases of measles. Last month there were recorded 1,005 cases of measles, and 246 of scarlatina. The cases of diphtheria numbered 214; typhoid, 346; and typhus, 50.

The Health of the Army.—Venereal, of the most virulent type, says the *Army and Navy Gazette*, is still the prevailing disease among the troops at all the military stations. At Aldershot, considerably more than one-half the patients in hospital are suffering from this disease, which is steadily on the increase. On the other hand, the Lock hospitals are almost empty. Attendance at these institutions being now optional, but few unfortunates present themselves for treatment; and these, as as a rule, are only very bad cases. Fostered and encouraged as it is, this loathsome disease is spreading to such an extent as to cause grave anxiety.

Cambridge University.—The Regius Professor of Physic (Professor Paget) will begin his lectures on the Principles and Practice of Physic on Monday, January 28, Subject for the term: "The Causation of Diseases and Elements of Hygiene." The Professor of Surgery (Professor Humphry) gives notice that his lectures on the Principles of Surgery will commence on Thursday, January 24. The Professor of Chemistry gives notice that his lectures on the General Principles of Chemistry will begin on Thursday, January 24. The Jacksonian Professor gives notice that he will lecture during the Lent term on Organic Chemistry; the lectures will begin on Monday, January 28.

The Dublin Artisans' Dwellings Company. — On Monday, the 14th instant, a number of prizes were distributed to the occupiers of the houses and cottages, the property of this company, by Lady Kathleen Brabazon, daughter of the Earl of Meath. Dr. Grimshaw, the Registrar-General for Ireland, read the report of the judges, from which it appeared that, in all the groups of buildings except the Coombe, there was a somewhat lessened competition for the prizes. It was deemed advisable to exclude from competition for one year the winners of a first prize, as the unsuccessful candidates were apparently hanging back from a renewed competition in consequence of their failure. The judges noticed that in several instances there was a tendency to sacrifice the health and comfort of the house to accommodation for flowers.

Parkes Museum Lectures.—On Thursday, the 17th instant, Mr. Pridgin Teale delivered his lecture on "Economy of Coal in private houses." He enunciated the following rules for the construction of a fireplace, with a view to the economy of coal consumption and the abatement of smoke: —1. As much firebrick and as little iron as possible. 2. The back and sides of the fireplace should be firebrick. 3. The back of the fireplace should lean or arch over the fire so as to become heated by the rising flame. 4. The bottom of the fire or grating should be deep from before backwards, probably not less than 9in. for a small room, nor more than 11in. for a large room. 5. The slits in the grating should be narrow—perhaps ¼in. wide for a sitting-room grate, ⅜in. for a kitchen grate. 6. The bars in front should be narrow. 7. The chamber beneath the fire should be closed in front by a shield or economiser.

University of Edinburgh.—At a crowded and enthusiastic meeting held at Edinburgh on Thursday, the 17th instant, a "Students' Representative Council" was founded, and a provisional committee elected. The object of the association is to consolidate together the students of different faculties into a corporate whole, to encourage social intercourse between them, and to watch over their interests as a body.

Army Medical Department. — Surgeon-Major W. Temple, V.C., has been appointed secretary to the principal medical officer in India, in succession to Deputy-Surgeon-General Wolseley, who proceeds to England.

Fever at Aldershot.—Enteric fever has broken out among the troops in the permanent infantry barracks at Aldershot, and several serious cases have already been sent to the second Station Hospital. All the huts in the south camp, some of which are said to be in a very dilapidated condition, have been inspected. These huts were condemned years ago as unhealthy, while the brick buildings recently erected are allowed to remain empty.

Vaccination Grant.—Dr. Thomas Dutton has obtained the Public Vaccination Grant of £7 4s. for successful vaccination in the Manhood District, Westhampnett Union.

CHARGE AGAINST A MEDICAL PRACTITIONER.—On Monday, the Anglesey magistrates committed for trial at the assizes Dr. Roland Williams, a surgeon practising at Holyhead, on a charge of issuing a false certificate of death, with intent to defraud the Royal Liver Friendly Society of Liverpool.

THE LATE MR. WHEATLEY. At a special meeting of the Council of the Royal Medical and Chirurgical Society, on the 17th instant, the following resolution was passed unanimously :—

"The Council of the Royal Medical and Chirurgical Society of London desire to express their sorrow at the sudden and unexpected death of their late excellent Resident Librarian, Mr. Benjamin Robert Wheatley, and their sympathy with the surviving members of his family. The Council also wish to record their deep sense of the value of his services to the Society during the last forty years, and their due appreciation of his constancy and fidelity in the discharge of his important duties." We understand that it is contemplated to establish a memorial of the Society's sense of the unsurpassed devotion which the late Resident Librarian applied to the conduct of the Royal Medical and Chirurgical Society's affairs.

LUNACY BOARD OF LANARKSHIRE.—A deputation from the Lunacy Board of Lanarkshire has been visiting a number of asylums in England during the past fortnight, for the purpose of making themselves familiar with the latest improvements in the construction and management of houses for the insane. The visit has reference to the county asylum which it is proposed to erect. The Board are in expectation that the deputation will bring back some useful suggestion.

MANCHESTER MEDICAL SOCIETY (MICROSCOPICAL SECTION.)—At the Annual Meeting of the Microscopical Section, which was held at Owens College on the 15th instant, the following were elected officers for 1884 :—

President—Dr. H. Ashby.
Vice-President—Dr. J. Dreschfeld.
Committee—Dr. J. Dixon Mann, Mr. Broadbent, Mr. A. W. Stocks, Dr. A. H. Griffith, Dr. H. Tomkins, Dr. H. R. Hutton.
Treasurer—Dr. J. S. Bury.
Secretary—Mr. A. H. Young, 96, Mosley Street.

GLASGOW ASYLUM FOR THE BLIND.—The annual meeting of the subscribers was held on Monday, 21st inst. The secretary's report showed that 76 blind persons, not resident in the asylum, had been employed in the manufacturing department of the institution, while the number of residents numbered 72. There were also six children in attendance at the school, but not in residence, so that in all 154 persons were participating in the benefits of the institution. An urgent appeal was made for increased liberality on the part of the public.

COLLEGIATE LECTURES.—Professor Parker, F.R.S., will commence his course of nine lectures on "Mammalian Descent" in the Theatre of the Royal College of Surgeons, on Monday, February 4, and continue the same each Monday, Wednesday, and Friday, at 4 o'clock; Professor Flower, F.R.S., will follow with his course of nine lectures on "The Principal Types of the Human Form;" he will be succeeded by Mr. Frederic S. Eve, F.R.C.S. (Erasmus Wilson Lecturer), who will give three demonstrations "On Some Points in Pathology, illustrated by specimens from the College Museum;" Professor Sir Henry Thompson will then deliver six lectures on "Some important points in connexion with the Surgery of the Urinary Organs." The courses will be brought to a close by Mr. Edward A. Schäfer, F.R.S., who will deliver three lectures, the subject and dates of which will be duly announced.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—The following gentlemen passed their primary examinations in Anatomy and Physiology at a meeting of the Board of Examiners on the 17th inst., and when eligible will be admitted to the pass examination, viz.—

Brodie, F. Carden, of the Middlesex Hospital.
Clarke, S. A., of St. Mary's Hospital.
Cuslahan, Archibald, of Guy's Hospital.
Holman, E. K., of Guy's Hospital.
Levy, Henry, student of St. Thomas's Hospital.
Quartley, S. Warner, of the Middlesex Hospital.
Stelfox, Harold, of Guy's Hospital.
Turner, J. Rowland, of the Sheffield School of Medicine.
Veram, E. Lawrence, of St. Bartholomew's Hospital.
Williams, William, of St. Mary's Hospital.
Wilson, Samuel, student of St. Thomas's Hospital.
Winterburn, J. Williamson, of the Manchester School of Medicine.
Wynter, A. Ellis, of St. Bartholomew's Hospital.

Six candidates were referred for three months, and one for six months.

The following gentlemen, having undergone the necessary examinations for the diploma, were admitted Members of the College at a meeting of the Court of Examiners on the 21st inst., viz.—

Anderson, F. U., L.R.C.P. Edin., Halifax, of the Halifax Hospital
Bell, J., L.R.C.P. Lond., Albert Street, N.W., of University College Hospital.
Bradshaw, T. B., M.B. Dub., Ampthill Square, of the Dublin School.
Edwards, W. L., L.R.C.P. Lond., Carmarthen, of the London Hospital.
Harris, C. J. J., L.S.A., Wandsworth Common, of the Charing Cross Hospital.
Harris, J. W., L.S.A., Ivybridge, Devon, of Guy's Hospital.
Hoffmeister, G. B., B.A. Cantab., Furnival's Inn, of St. Bartholomew's Hospital.
Kirby, E. D., M.B. Edin., Leamington, of the London Hospital.
Kite, E. W. D., L.S.A., West Bromwich, of the Birmingham School.
Ley, H. J., M.B. Edin., Teignmouth, Devon, of the University of Edinburgh.
Mackay, N.E., M.D., Halifax, of the Halifax Hospital.
Minter, E. D., L.R.C.P. Edin., Plympton, of Guy's Hospital.
Myles, G. T., L.R.C.P. Edin., Bristol, of the Bristol School.
Prendergast, J. J., L.R.C.P. Edin., Melbourne, of the Melbourne School.
Ridley, G. W., M.B. Durham, Newcastle-on-Tyne, of the Newcastle School.
Scott, A. W., L.S.A., Stourbridge, of the Birmingham School.
Sheppard, H. A., L.S.A., Southampton, of the Charing Cross Hospital.
Webster, T., L.S.A., Bewdley, of King's College Hospital.
Williams, G. H., L.R.C.P. Edin., Warrington, of the Manchester School.
Young, C. S., L.S.A. Dundee, of the Glasgow School.

Seven candidates, having failed to acquit themselves to the satisfaction of the Court of Examiners, were referred to their professional studies for six months, and one for three months.

The following gentlemen passed on the 22nd instant, viz. :—

Aitken, W. B., M.B. Glasgow, Dalry, Ayrshire, of the Glasgow School.
Bean, W. H., L.S.A., Colchester, of the Charing Cross Hospital.
Buxton, W. M., M.B. Durham, Alderney Road, E., of the Newcastle School.
Francis, W. H., M.B. Edin., Coquimbo, Chili, of the Edinburgh School.
Jackson, A. H., L.R.C.P. Edin., Holtham Road, N.W., of Guy's Hospital.
Jefferson, R. P., Leeds, of the Leeds School.
Kendal, A. S., M.D., Belle Vue Medical College, Sydney, N.S.W., of the Halifax School.
Lawrence, L. A., L.S.A., Belsize Avenue, N., of St. Bartholomew's Hospital.
Parsons, J. P., M.B. Durham, Blackheath, of Guy's Hospital.
Scott, J., B.A. Cantab., Barnard's Inn, of St. Bartholomew's Hospital.
Spicer, F., M.B. Durham, Carleton Road, N., of St. Bartholomew's Hospital.
Tayler, H. P., B.A. Cantab., Barnard's Inn, of St. Bartholomew's Hospital.

Five candidates were approved in Surgery, and when qualified in Medicine will be admitted Members of the College. Ten candidates, having failed to acquit themselves to the satisfaction of the Court of Examiners, were referred to their professional studies for six months, and three months.

The following gentlemen passed on the 23rd instant, viz. :—

Hunt, B., B.A. Oxon, Oxford, student of St. Bartholomew's Hospital.
Kebbell, C., Brighton, student of St. Bartholomew's Hospital.
Koettlitz, R., Dover, of Guy's Hospital.
Lankester, A. O., Belsize Park, student of St. Bartholomew's Hospital.

Six candidates who passed in Surgery at previous meetings of the Court, having subsequently obtained Medical qualifications, were admitted Members of the College, viz. :—

Bradbrook, W., L.S.A., Green Street, E., of the London Hospital.
Saunders, J. F., L.S.A., Gravesend, of Guy's Hospital.
Sheldrake, E. N., L.R.C.P. Lond., Albion Street, W., of the University College Hospital.

Tilley, W. J., L.R.C.P. Lond., Shepherd's Bush Green, of the University College Hospital.
Weller, C. J., L.R.C.P. Lond., Coleshill Street, W., of St. George's Hospital.
Wnyon, E. J., M.B. Lond., Conisclife, near Darlington, of Guy's Hospital.

Five candidates passed the examination in Surgery, and, when qualified in Medicine and Midwifery, will be admitted Members of the College; eleven candidates were referred for six months, and four for three months.

APOTHECARIES' HALL.—The following gentlemen passed their examination in the Science and Practice of Medicine, and received Certificates to Practise, on Thursday, 17th instant:—

Ingle, Arnold Clarkson, Regent Street, Cambridge.
Saunders, James Fredk., Park Place, Gravesend.

The following gentleman also on the same day passed the Primary Professional Examination:—

Dow, Hugh Aitken, Edinburgh University.

KING AND QUEEN'S COLLEGE OF PHYSICIANS IN IRELAND.—An examination for the Membership took place on Monday and Tuesday, January 7th and 8th, when the following candidates were successful:—

Henry Colpoys Tweedy, M.D., Dubl., 1874; F.R.C.S.I., 1873; L.K.Q.C.P., 1880.
Stewart Woodhouse, M.D., Dubl., 1874; L.R.C.S.I., 1872; L.K.Q.C.P., 1880.

A Quarterly First Professional Examination was held on Monday, January 7th, and following days, when the undermentioned candidates were successful:—

Beilby, Elizabeth, London.
Fox, William Joseph, Dublin.

The usual Monthly Examination for the Licenses of the College took place on Monday, January 7th, and following days. The undermentioned candidate obtained the Licenses in Medicine and Midwifery:—

Coffey, Joseph.

THE CASE OF MESSRS. BOWER AND KEATES.

The Committee desire to give notice that no more signatures to the memorial, or contributions to the Indemnity Fund, can be received after this day (Saturday, Jan. 26th).

The sum of £13 2*s.* 6*d.* has been forwarded to the Committee by the York Medical Society, subscribed by the following:—T. Anderson, M.D.; R. Baker, M.D.; A. Ball, Esq.; W. Banks, M.B.; Surgeon Beamish, A.M.D.; W. von Beverhondt, Esq.; Surgeon Cream, A.M.D.; W. Draper, Esq.; H. Fitzsimons, M.D.; J. T. Hingston, Esq.; R. Hewetson, Esq.; C. K. Hitchcock, M.D.; W. H. Jalland, F.R.C.S.; T. Kirsopp, M.B.; A. Jefferson, Esq.; E. Morganrood, Esq.; S. W. North, Esq.; R. Petch, M.D.; J. Ramsay, M.D.; Surgeon-Major Riordan, A.M.D.; F. Shann, Esq.; W. A. Shann, M.B.; H. C. Shann, Esq.; H. E. Spencer, Esq.; F. H. Weekes, Esq.; I. M. Williams, Esq.

The following is the seventh list of contributions, being those received between the 12th and 21st inst.:—

H. Gervis, M.D., £5 5*s.*; Reynolds E. Ray, Esq., £2 2*s.*; J. Burdon Sanderson, M.D., F.R.S., £2 2*s.*

The following have sent one guinea each:—J. Airey, Esq.; J. Brands Allan, M.D.; W. Bruce, M.D.; E. Carver, M.A., F.R.C.S.; F. H. Elliott, M.D.; Jas. Ellison, M.D.; Chas. Hutton, M.D.; W. F. Johnson, Esq.; W. H. Rix, Esq.; W. Sutton, M.D.

Henry Viant, Esq., £1.

The following have sent half a guinea each:—W. Wightman Cooper, Esq.; J. K. Milne, M.D.; J. G. Fitzgerald, Esq.

The following have sent ten shillings each:—Bushell Anningson, M.D.; J. B. Collins, Esq.; J. S. Harris, Esq.; J. T. Hartill, Esq.; J. Wale Hicks, M.A., M.D.; J. D. James, Esq.; W. H. Platt, Esq.; John Scott, M.D.; J. Brooks Shepherd, Esq.

The following have sent five shillings each:—W. Stirling Anderson, M.D.; Alfred Clark, Esq.; A. E. Clark, M.D.; C. E. Douglas, M.D.; G. P. Francis, Esq.; E. V. Hemingway, Esq.; W. Hugh Hughes, Esq.; W. Grant Jones, Esq.; R. Hosking, Esq.; S. R. Lovett, Esq.; W. A. Martin, Esq.; G. H. Maskelyne, Esq; A. Ross Paterson, M.D.; J. T. H. Sealy, Esq.; T. Percy Taylor, Esq.; Jas. Titley, M.D.; R. S. Veale, M.D.

The following have sent two shillings and sixpence each:—W. Marston Clark, Esq.; R. Earlam, Esq.; R. Erskine, M.D.; H. F. Hann, Esq.; Geo. Locke, Esq.; J. Foster Palmer, Esq.

Errata.—"W. Bucknill, Esq.," acknowledged last week, should be "J. C. Bucknill, M.D., F.R.S."; "E. Owles" should be "Edmund Owen, F.R.C.S."; and "J. Jones" should be "Sydney Jones, F.R.C.S." C. S. A. Atkinson, Esq., ten shillings, received on the 2nd instant, was inadvertently omitted in the previous list.

F. A. MAHOMED, R. W. BURNET, } *Hon. Secs.*

APPOINTMENTS.

APTHORP, F. W., M.R.C.S., L.R.C.P.—Admiralty-Surgeon and Agent to the Chichester Harbour Division, *vice* Thomas Dutton, M.D., M.B., M.R.C.P., resigned.
BLORE, ISAAC, M.B.—Resident Medical Officer to the Leeds Fever Hospital.
FISHER, S. WINTER, M.D.—Honorary Physician in Ordinary to the Brighton and Home Dispensary, *vice* Dr. Tyler Smith, resigned.
GREENWOOD, CECIL D., M.R.C.S. Eng., L.S.A.—To the Yoxall District, Lichfield Union.
HOWARD, WILFRED, M.R.C.S. Eng., L.R.C.P. Edin.—To the South Welney District, Downham Union.
JACKSON, C., L.R.C.P.—Medical Officer for the Rainton District of the Houghton-le-Spring Union.
JAGO, EDWIN O., M.R.C.S. Eng., L.S.A.—To the Cadishead District, Barton-upon-Irwell Union.
KING, ARTHUR, M.B.C.M. Edin.—To the Aspley Guise District, Woburn Union.
LARDER, H., M.R.C.S., L.S.A.—Assistant Medical Officer to the St. Marylebone Infirmary, Notting Hill.
LUCAS, ARTHUR, M.R.C.S. Eng., L.S.A.—To the Workhouse, Woburn Union.
MOLONY, FITZJAMES, L.R.C.S. Ire., L.K. & Q. Coll. Phys. Ire.—To the Porlock District, Williton Union.
ROBERTS, H. W., M.R.C.S., L.S.A.—Divisional Surgeon to the Brockley Police Station.
SCANLAN, ARTHUR DE COURCY, M.R.C.S., L.S.A.—House-Surgeon to the Royal Westminster Ophthalmic Hospital, *vice* Mr. Willoughby, resigned.
SHAW, J. A., M.R.C.S., L.S.A.—Registrar to the Victoria Hospital for Children, Queen's Road, Chelsea, *vice* B. N. Rake, M.B. Lond.
SPEIRS, W., M.R.C.S., L.R.C.P., &c.—Certifying Factory Surgeon for the District of Cleator Moor, Cumberland, *vice* Dr. Syme, deceased.
WHITE, WM. R., M.D., M.C. Aber., M.R.C.S. Eng., L.S.A.—To the Wadhurst District, Ticehurst Union.

DEATHS.

FORTESCUE, WILLIAM, F.R.C.S., at Albert-road, South Norwood, on January 15, in his 71st year.

VACANCIES.

HOSPITAL FOR SICK CHILDREN, 49, GREAT ORMOND STREET, BLOOMSBURY.—Assistant Surgeon. For particulars see Advertisement.
TAUNTON UNION.—The office of Medical Officer of the workhouse is vacant by the resignation of Mr. S. Farrant. Salary £63 10s.
WESTERN GENERAL DISPENSARY, GERRARD-STREET, SOHO.—Physician. Candidates must be Doctors or Bachelors of Medicine and registered practitioners. Diplomas and testimonals to be sent, under cover, addressed to the Secretary, on or before January 29. The election will take place on January 31.

NOTES, QUERIES, AND REPLIES.

Collegiate Examinations.—At the pass examination for the diploma of membership of the Royal College of Surgeons, which was commenced on the 18th instant, 191 candidates presented themselves, as against 175 the corresponding period last year. The following were the questions on surgical anatomy, and the principles and practice of surgery, submitted to the candidates at the written examination on the 18th instant, when they were required to answer at least four out of the six questions, including one of the first two, between 1.30 and 4.30 P.M., viz.:—1. Describe the operation of tying the Common Carotid Artery. Give the anatomical relations of the vessel in the Neck. Mention the anastomoses for carrying on the circulation. 2. The Male Urethra being laid open along its upper surface in its entire course, describe the parts exposed to view. Give the relative dimensions of its various regions. Name the situations most prone to injury and disease. 3. Describe an ordinary case of suicidal "Cut Throat." Give the treatment, immediate and remote, with any complications which may occur. 4. In what way does a Strangulated differ from an Obstructed (Incarcerated) Hernia? Give the symptoms and appropriate treatment of each condition. 5. What parts are most frequently affected by Epithelial Cancer? Mention its most common local causes. Sketch its pathology and treatment. 6. Explain briefly the following terms:—Cirsoid Aneurism; Pott's Fracture; Ectropion; Amussat's Operation; Ptosis; "Réduction en masse." The following were the questions on midwifery and the diseases of women, submitted to the candidates on Saturday, the 19th inst., when they were required to answer three out of the four questions between 12.30 and 2 o'clock P.M., viz.:—1. What discharges may take place from the Genital Canal during pregnancy? What are their causes? and how would you recognise them? 2. Describe the Mechanism of Labour, with the head presenting and the occiput posterior and to the right. 3. Describe the Cephalotribe, and mention the cases in which it is specially indicated. 4. What condi-

tions produce enlargement of the Cervix Uteri, and how would you distinguish between them? On the same day, between 2.30 and 4.30 P.M., those candidates who had not previously undergone any recognised examination on the Principles and Practice of Medicine, were required to answer three out of the four following questions, including No. 4, between 2.30 and 4.30 P.M., viz.:—1. What are the causes, anatomical characters, symptoms, physical signs, and treatment of Acute Pericarditis? 2. Give an account of the Clinical History of a typical case of Measles, and indicate the chief complications and sequelæ to be feared. How would you treat it; and what measures would you take to prevent the spread of the disease? 3. What are the causes of Pyloric Obstruction? Point out its pathological effects, symptoms, diagnosis, and treatment. 4. Mention the principal ingredients in the following Officinal Preparations, and give a concise account of their actions and therapeutic uses, with their doses:—Pulvis Jalapæ Compositus, Liquor Arsenicalis, Liquor Hydrargyri Perchloridi, Mistura Scammonii, Pilula Saponis composita, Mistura Ferri composita. At the primary, or anatomical and physiological, examinations, which were brought to a close on the 17th instant, 211 candidates had been examined, of which number no less than 79 were rejected, viz.:—66 for three months, and thirteen for six months. At the corresponding period last year there were 190 candidates, of which number 139 passed, 44 were referred for three months, and seven for six months.

Damages for Accidents during Anæsthesia.—A suit, brought against a dentist of New York for negligence in allowing a piece of tooth to drop into a patient's throat, which, after causing him to suffer with a cough, was expectorated at the end of a month, was recently decided against the defendant, who was obliged to pay 500 dollars damages. The case was made the subject of an appeal, but the judgment was sustained. This recalls the case of a boy who died while under the influeuce of nitrous oxide, being suffocated by a molar tooth, which slipped out of the forceps, and became impacted in the larynx. In such cases, a dentist should both be competent and willing to perform tracheotomy, for the patient will generally die of suffocation before a surgeon can be summoned.—*Philadelphia Med. Times*, Nov. 17.

Medical Women in the Olden Time.—It is not only at the present time that the Hippocratic art numbers its disciples among the female sex; for the *ancien regime* was quite familiar with the professional equality which the Press of our day chronicles as a novelty. For example, we have only to consult the *Calendrier Historique de la ville de Lyon* for 1735, to find at the end of a list of the 43 *maîtres chirurgicus*, and preceding that of the apothecaries, a list of 13 widows of surgeons. It would appear that at that period it was admitted that professional knowledge could be transmitted by cohabitation, inasmuch as these widows had the right to practice after the death of their husbands.—*Lyon Medical*, Jan. 13.

COMMUNICATIONS RECEIVED—

PROFESSOR LATHAM, Cambridge; Mr. CLEMENT LUCAS, London; Mr. HENRY MORRIS, London; Mr. BERKELEY HILL, London; Dr. PAUL KOVALENZKY, Charkoff, Russia; THE SECRETARY, ROYAL INSTITUTION, London; THE REGISTRAR-GENERAL FOR ENGLAND, London; Dr. MAHOMED, London; Dr. J. CLINICAL LECTURES

By J. MATTHEWS DUNCAN, M.D., F.R.S.,

Physician-accoucheur and Lecturer on Midwifery at St. Bartholomew's Hospital.

LECTURE V.—AMENORRHŒA AND VICARIOUS MENSTRUATION.

NOW-A-DAYS, we do not regard amenorrhœa as a grave disease, as our immediate ancestors did. Their views are, by inheritance, represented now chiefly by the opinions prevalent among women. As a rule, women do, in all circumstances, regard amenorrhœa as, in itself, a grave disease, pregnant with manifold and multiform disaster. The erroneous medical opinions of the public are a source of much evil, not to the public only, but specially also to the profession; and the errors have generally been impressed on the public mind by the doctors themselves, who find the uprooting of them a very slow process. Error is pregnant with evil fruit, produced now and ages hence. The doctors sow the wind and reap the whirlwind.

It may be doubted whether amenorrhœa is ever more than a negative symptom. Certainly, except perhaps in some exceptional instances, it should be regarded neither as a disease nor even a disorder. Often, as in wasting diseases, it is a beneficent arrangement, saving for the sufferer a considerable amount of energy and of blood. There are indeed many delicate weak women whose health would be improved in every way if they had amenorrhœa; and some modern enthusiasts would, for such women, recommend the operation of spaying. Many cases of so-called dysmenorrhœa are simply cases of ill health induced by menstruation; the weak girl has no energy to spare even for the normal process; when the time comes round, she gets languid, dark areas surround her eyes, her back aches and she is a patient; not, as she ought to be, a vigorous blooming woman, fit to endure menstruation, and fit also to go successfully through the tedious processes of pregnancy, parturition and suckling. In such women menstruation may be, almost truly, described as disease, just as pregnancy and parturition frequently are.

I do not, meantime at least, teach you that there is no such disease or disorder as amenorrhœa. The matter is as yet not clear enough for decided yea or nay. Two sets of cases occur where the amenorrhœa is probably morbid. First: you meet with healthy, robust women, who have for years menstruated regularly, and perhaps even borne a small number of children, and who now, while still young, do not menstruate. Such cases of annihilation of at least the visible parts of this process, and probably also of the ovulation or invisible part, seem to be no more: an arrest of a function which is justly expected to go on regularly in all healthy women, a sluggishness of the whole genital

system. Any disease or disorder complicating such amenorrhœa is likely to be regarded as a cause or as a consequence of it. Second: you have cases of bad health and specially of anæmia or chlorosis where the disorder is probably in some nervous genital centre, and whose chief manifest result is amenorrhœa. Anæmia or chlorosis from any cause may induce amenorrhœa; but there is a large class of cases where chlorosis seems to be not the cause of the amenorrhœa, but probably the result of it or rather of that derangement of nervous system which is evidenced by the amenorrhœa and chlorosis. In such cases you expect good from re-establishing (if you can) the menstrual function. Its return to regularity seems to bring with it a healthy hæmatosis. It is not cases of chlorosis only, in which this kind of amenorrhœa is believed to be present, cases also of dyspepsia, of constipation, of anorexia nervosa, and of other nervous disorders.

The commencement of menstruation may be long delayed, or the function may never be established—emansio mensium—a condition often the result or accompaniment of bad health, always a very important matter in social respects. Such women may have no internal genital organs, or only part of them, or only imperfectly developed organs; and there may be no ground for suspecting imperfection, the women being vigorous, and in all other respects fine specimens of the race. Of this you may remember a case lately in "Martha," where we could detect no genital organs internally by careful examination. Treatment for emansio is generally set agoing early and pursued diligently; and soon the question arises, how long is it to be pursued? There is little difficulty in the earlier years if the girl is chlorotic or otherwise in bad health, for these conditions urge the practitioner. There is little difficulty also, if the girl is ill developed in her general bodily figure, if she is still plainly a mere girl. But it soon, in all cases of entire absence of menses, becomes desirable to know whether or not she can menstruate or should be expected to menstruate; and this especially in robust healthy women. In any case it is common to delay local examination till the age of 19 or 20 is reached, and then it is done only with the approval of the patient. But necessity for examination may be precipitated by a proposal of marriage. A woman is not wise to marry who has imperfection of the genital organs. In ordinary circumstances regular menstruation is held as sufficient evidence of perfection. When menstruation has not been commenced it is necessary to make examination to ascertain if they are perfect in form and size so far as examination can decide. If they are well sized and well formed it is still a matter for consideration whether or not the married state should be entered upon. Were it certain that a woman who has never menstruated cannot bear a child, she should not be married, but it is known that, while pregnancy is not to be expected, it yet may occur and be successfully carried on.

I have said that the establishment of menstruation is held, in ordinary life, as sufficient evidence that a woman is marriageable so far as her genital organs are concerned. But this is not a warranted conclusion, and it remains as a practical guide only, because imperfection is very uncommon, and still more rare in women who menstruate. It is a very interesting and still unsolved question—how small a womb can be successfully pregnant. Certain it is, that a very small one may be unsuccessfully pregnant. Long ago I published a case, where the womb was well ascertained to be not above two inches in length from os externum to inside of fundus. This woman was repeatedly pregnant, and had early abortions, and in one of these, which I examined, there was marked hypoplasia of the decidua. Under the influence of repeated pregnancies the woman's womb did not increase in size—it remained an undersized organ. It has been fondly imagined that a womb may be made to grow—a natural or healthy growth—and to menstruate—not merely bleed a little—by irritating it with intra-uterine pessaries: but there appears to me no rationality in such expectations, and I advise you not to resort to such treatment. There are other evident objections to it besides the danger of it inducing inflammation, and even causing death. If repeated pregnancies do not make a womb grow to its natural bulk, a rod of metal inserted into it is not likely to make it grow or to do anything but harm.

While, with the restriction stated, regular menstruation is held as evidence of marriageableness, you must not hold that absence of menstruation is proof of the opposite. A woman may have every quality or attribute of marriageableness who menstruates irregularly, or rarely, or even who has never menstruated at all.

The commonest form of amenorrhœa is that of young girls still in their teens, or only lately past them, with chlorosis or green sickness as well as cessation of menstruation; and, whatever may be the true theory of such cases, we, in practice, regard and treat them simply as cases of chlorosis. The condition is very frequent among girls brought from the country to boarding-schools in town, or to domestic service; both modes of life implying a large amount of work, with deficiency of open fresh air and of bodily exercise. In whatever manner produced, the disease is of great importance, leading, as it sometimes does, to disease of the heart, to renal disease, or to phthisis pulmonalis.

The girl becomes languid, the skin, especially of the face, becoming pale and dull, or even very slightly greenish, the lips and mucous membranes generally pale, the appetite bad or curious, the tongue foul, the bowels torpid, the fæces scanty, dark coloured, hard, the pulse quick, the heart easily made to palpitate, the breath easily made short. Sometimes there is puffiness of the face, and particularly of the eyelids; and sometimes anasarca, affecting, of course, chiefly the lower limbs. This state may disappear quickly, or be easily cured; or it may persist long, or be only partially cured. Some cases do not get right till after one or more pregnancies. Some cases become inveterate, or are so from the first—and there have been found, in some rare instances of this kind, malformations of internal organs, specially of the heart and arteries.

Of quite another pathology, are cases of what is called suppression of menses. This has nothing to do with anæmia or chlorosis, but rather with morbid congestion or inflammation of the internal genital organs. A girl in the early days of menstruation, or in the days immediately preceding, is exposed to cold, it may be has had wet and cold feet: the flow of menses is quickly and prematurely arrested, or does not come on: there is more or less pain in the lower belly and sacrache: there may be more or less of fever. Amenorrhœa thus suddenly begun may not recur, or it may persist for many months, or instead of amenorrhœa there may be great irregularity of menstruation.

Such cases are to be managed and treated as cases of more or less grave inflammation—confinement to bed, laxatives, diaphoretics, poulticing the hypogastrium. Free loss of blood by menstruation is desirable, and the poulticing may favour it: or, if it does not come, three or four leeches may be applied to the perineum. When the next molimen menstruale shows itself, great care is to be to taken to encourage the appearance of the menses and promote copious flow, by rest and warmth.

The aim of treatment in amenorrhœa by suppression, is to moderate or diminish congestion. In ordinary amenorrhœa, from uterine sluggishness, or from chlorosis, the aim is to stimulate the generative organs, to produce or increase congestion. Cases of this latter kind may be completely amenorrhœal, or the menses may be scanty, or, instead of bloody discharge, there

may be only temporarily increased mucous discharges —whites. There may be a molimen or no molimen. When there is said to be a molimen or attempt, the girl expects the flow, or knows by her feelings that it should come : the feelings being scarcely describable, often backache or sacrache, or aching in the thighs, or headache, peculiar feelings in the throat, dark areas appearing around the eyes. All this is regarded surely as a molimen if it comes at the proper calculated monthly time. In the worst cases there is no evidence of molimen whatever.

If there is a molimen it is common to invite the flow by treatment—popular, old, sanctioned by Hippocrates. The feet are plunged in water as hot as it can be borne, and it is common to make the stimulus more lasting by adding mustard to it. After this pediluvium, the girl is made warm in bed and has a pretty strong dose of alcohol in some pleasant form—gin and hot water and sugar being a favourite ; and it gets the grand medical designation of a diffusible stimulant. Often this is followed by the desired result. The modern introduction of hip baths has led to the frequent substitution of these for the Hippocratic pediluvium, and I believe this is a mistake ; it is the pediluvium that has virtue, not a full bath nor a hip-bath.

In addition to this treatment of the molimen it is common to give for two or three days, that is, while the molimen lasts, some other stimulant which appears to favour the appearance of the flow or to increase its quantity. There are many in use. That which I like best is oil of pennyroyal, a drop in some vehicle several times a day.

When a woman has the molimen she is held to be truly menstruating in all respects except that blood does not flow. Treatment may be useful, and be, in a very limited sense, described as emmenagogue, driving out the menses.

When there is no molimen you are told to treat by emmenagogues, and I believe this is not desirable. There are indeed no emmenagogues, for that word implies not mere favouring an expected and imminent flow as announced by a molimen, but the production of menstruation, molimen, flow, and ovulation, all together by specific medicines, not by erotic excitement or improvement of health.

If you give an amenorrhœal woman savine or cantharides in large doses, the most powerful of so-called emmenagogues, you may, no doubt, cause blood to flow from the womb ; but this is not only a caricature of menstruation, it is also an unmixed injury to the woman. The same medicines given to man or woman may cause strangury and hæmaturia, and that is not menstruation ; nor is metrostaxis or bloody flow from the womb. Equally unreasonable are attempts to induce menstruation by scarifying the cervix uteri, or by cupping the interior of the body of the uterus.

I have told you that we do not know any drug that has a really emmenagogue action in the sense of originating or favouring the healthy complex proceedings of which menstrual flow is a part. The pharmacopœia has many, but they are not be trusted, rather eschewed. The only emmenagogue medicine that I know is not to be found in the pharmacopœia : it is erotic excitement.

Of the value of erotic excitement there is no doubt, but it is only in a modified and carefully considered way that you can use it remedially. There are many points at which medicine and morals come into contact, and their consideration is most important. A long lecture might indeed, with great advantage, be given to you describing the mutual relations of the one to the other, and especially, with a view to our present subject, the therapeutical power of morals in medicine and the therapeutical power of medicine in morals. I pass it all over, only asking you to be in a high sense wise in your meddling in such matters.

3

In ordinary practice the physician trusts almost exclusively to means for restoring and maintaining general health, and in particular to remove the chlorotic condition or restore the function of blood-formation. He has to enter fully into matters of education—of diet—of regimen. He regulates the bowels by what are called warm purgatives—myrrh and aloes. He persistently administers chalybeates in varied forms.

The woman's plan, or her mother's or guardian's, is to re-establish menstruation, being sure that, if this is done, all will be right, all disorders will disappear. The wise practitioner does, in most cases, recognise the restoration of menses as the harbinger of cure of all the intertwined disorders ; but his theory is not that of the mother or guardian. His plan is to re-establish the general health, being sure that, when this is done, menstruation will reappear and the connected disorders disappear.

Finally, remember that sometimes, in chlorotic cases, menorrhagia takes the place of amenorrhœa ; and this kind of case is worse than the amenorrhœal. The watery blood flows too copiously. The watery blood favours the menorrhagia, and the menorrhagia increases the wateriness of the blood. A vicious circle.

Before concluding I shall add a few remarks on vicarious menstruation. Lately we had a case sent us of a young girl whose adviser regarded a recurrent copious spotted purpura, as an example of the disease, and as an object of interest we kept her in "Martha" for many weeks. The purpura quickly disappeared under our good diet ; but the girl did not menstruate, and there was also no reappearance of the rash. Besides, its history shewed no regular periodicity.

It was long, and till recent times, generally believed that by menstruation a woman got rid of some poison, and that Nature, failing to get it out in the natural way, sometimes succeeded in eliminating it by bleeding from a vicarious channel—the skin, an ulcer, the stomach, the lungs, or any part. This was vicarious menstruation ; and in my opinion it is high time to give up the whole disease as a tissue of error if not of absurdity. I have all my life been on the look-out for it, but I have never seen an example, and do not expect to do so. Many cases so-called have been brought under my notice, but none have survived a criticism of the simplest, not of a rigorous kind. Some cases have been coincidences, some bad or not sufficiently careful observations, some ludicrous mistakes. Of these last I may mention one sent to me by an eminent obstetrical friend who knew my incredulity. She had had amenorrhœa for six months, and had spat blood, it was said, every four weeks during the same six months. I asked her to come to me when the hæmoptysis returned. She did come, but the hæmoptysis had not returned. She said it did not regularly come at the four week times, and she expected it soon. I found her seven months pregnant and in perfect health.

No doubt bleedings may occur at what should be menstrual times, or at actual menstrual times, but that is far from being any kind of menstruation or representation of it. If there is a surface weak or predisposed to bleed, it may bleed during the excitement of a period, especially if it is the case that before or at the time the general blood pressure is increased. Such bleeding is not vicarious menstruation in any sense worthy of consideration.

DUNDEE SANITARY ASSOCIATION.—A society with this name has been formed at Dundee, the object of which is to enable members to procure practical advice, on moderate terms, as to the best means of remedying defects in houses of the poorer class in which they are interested, as well as to ensure the proper sanitary condition of their own dwellings, and to promote sanitary reform.

CONSIDERATIONS CONCERNING THE HYPOTHESIS OF NERVE-CENTRES, LEADING TO OBSERVATION AND EXPERIMENT.

By FRANCIS WARNER, M.D. Lond., F.R.C.P.,

Assistant Physician and Lecturer on Botany at the London Hospital; Assistant Physician to the East London Hospital for Children.

In the attempt to deal with an intricate problem, it is necessary to establish a mode of procedure, or definite line of enquiry, and for this purpose a working hypothesis is often wanted. Such an hypothesis is not necessarily intended to express an ultimate truth, but is intended, according to the knowledge possessed at the time, to be the best means available of expressing ideas as to what appears to be the truth, or at least a doctrine closely connected with the truth.

Thus, in speaking of nerve-centres in the brain, we do not here wish to express the belief that these necessarily exist as localised anatomical areas of brain tissue separate from the surrounding nerve-mechanism, although this may be true; I think that we may frame a definition without implying such anatomical isolation as an essential fact. The term nerve-centre is here used to imply "a portion of the nerve-mechanism, which can act more or less independently of the rest, and which by its activity produces certain more or less definite motor, or other effects, observable and separable from those of the rest of the central mass of the nerve-mechanism."

An hypothesis is useful, if it leads to systematic experimentation, and the record of observations, and I trust to be able to show that certain propositions may be defined and investigated by means of this working hypothesis. The form in which the definition or explanation of the term "nerve-centre" has been given makes a tacit assumption. It may be well to put forward as a postulate the assumption implied. It may be asked, how can we tell whether any portions of the central nerve-mechanism do act alone independently of the rest, as is tacitly assumed in defining a nerve-centre?

The postulate involved is as follows:—

Postulate I. "If we see some limited and definite nerve-muscular action often repeated, in the same and in different subjects, we may assume that there is some nerve-centre, or portion of the nerve-mechanism corresponding, which can and does act independently of the rest."

No movement can occur without a stimulus from some nerve-cells. The assumption is made that not only does one centre produce one set of movements, but also that the particular set of movements indicates the action of that particular centre. This assumption is also made in the ordinary methods of localising brain lesions and brain functions. In order to be quite clear in proceeding to a practical method of enquiry, we may repeat the last statement in the form of a postulate, one that is by most taken for granted.

Postulate II. "In conditions of health, one centre produces by its activity one particular set of movements which result from its action. Conversely the recurrence of that particular set of movements usually implies and indicates the activity of that particular nerve-centre whose action corresponds to those movements."

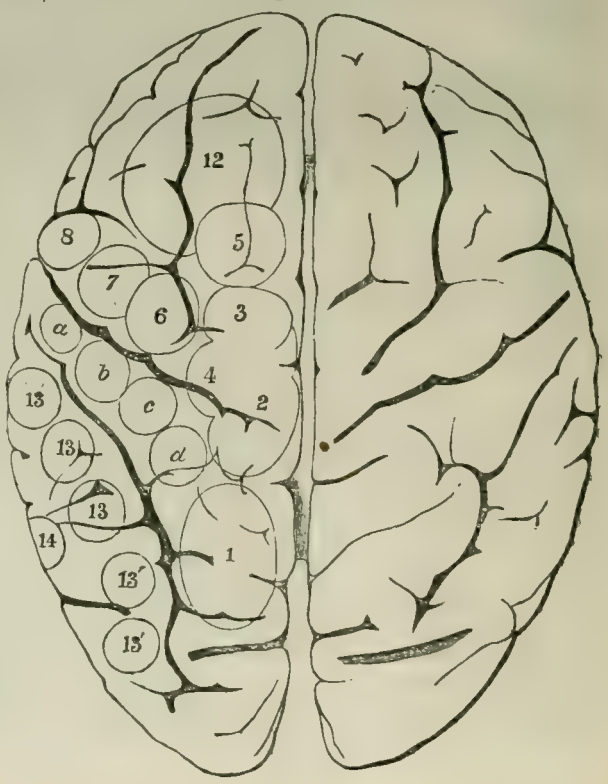
There is a slight difference in the mode of expression used in the paragraph above and in Postulate I.: it seems to me a point as yet not settled for all cases, whether it be certain that one kind of movement can only be produced by one centre; there appears much evidence to the contrary. It seems, however, exceedingly probable that the same movement may often be produced by different portions of nerve-mechanism in disease; still it seems likely that in health the same movement implies the activity of the same centre, for it is not likely that the same movement is produced with equal ease and economy by two different centres, and under ordinary circumstances the centre which most easily performs the work would act most spontaneously. It is not suggested that in all cases, and under all circumstances, one portion of the nerve-mechanism necessarily corresponds to, and sends motor force to, only one set of muscles, but that one part of the nerve-mechanism always produces the same movements *when it acts alone*, and that a simple isolated movement is usually the outcome of the action of the same centre.

It is assumed, then, that there exists a special centre, consisting of a group of cells, or a more or less independent piece of nerve-mechanism corresponding to each isolated movement. The probability of this being true is strengthened in any individual case where it can be shown that there are examples of isolated paralysis and examples of isolated excitation of such hypothetical centre.

Excitation of certain brain areas produces well marked muscular movements, and this indicates, if the data be reliable, the site of the centre corresponding to these movements. The same brain centre may be irritated by a pathological lesion demonstrable *post mortem*, the irritation causing muscular contraction, while a destructive lesion may cause paralysis of the same muscular movements as were active when the centre was irritated. So in Ferrier's experiments, irritation of a centre caused contraction in certain corresponding muscles, destruction of this centre caused palsy of the same movements. Here the definite nerve-muscular movement indicates the action of a definite or local area of brain or nerve-centre.

Fig. III. is from a block kindly lent me by Dr. D. Ferrier. (*See* his work, "The Functions of the Brain.")

Fig. III.



Upper surface of the brain, (7) and (8) centres for the elevators and depressors of the angle of the mouth respectively, (11) the centre of the platysma, retraction of the angle of the mouth. (*See* Ferrier's work, p. 143.)

In the Postulate I. it is assumed that every nerve-muscular movement is due to the action of a nerve-centre.

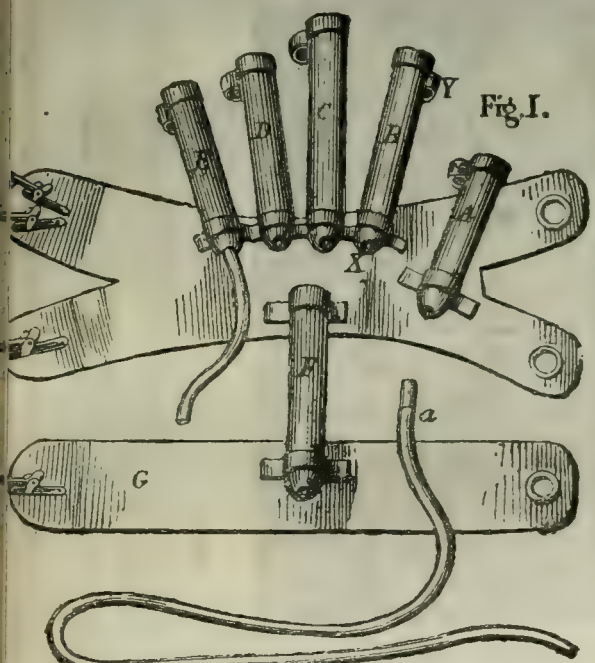
Now to further illustrate the postulates, and the propositions to which they lead us. A man can hold out his arm, then bend his wrist to any angle within anatomical limits, and keep it rigid in that position. It will be granted according to the postulates that this power of movement is due to the nerve-muscular system, and that some portion of the central nerve-mechanism must be the active cause of this movement, also that some nerve-centre must be the cause of the active fixed condition shown in the balance of the muscles producing the wrist posture.

Again, while the wrist is thus held bent, one finger can be flexed and moved separately and independently, showing that the nerve-centres for the movements of each finger can act separately and independently of the nerve-mechanism for the movements of the wrist.

Before discussing certain physiological propositions, it may be as well to say a few words as to the experimental methods which it is proposed to employ in trying to solve such problems.

The apparatus[1] employed consists of :

Fig. I.



1. A "motor," made of india-rubber, to be attached to the hand, one tube to each finger, or moving part (Fig. I, A, B, C, &c.). From these, pieces of thin conducting-tube (*a*, *b*, *c*) carry air to a set of recording tambours.

2. A frame supporting the recording tambours and electrical signals (Fig. II.).

Several propositions concerning nerve-centres of practical physiological interest may now be advanced.

1. Are there many nerve-centres that can, and often do, act separately and independently of each other?

[1] Towards the expenses of this apparatus a grant was made by the British Medical Association, on the recommendation of the Scientific Grants Committee.

Fig. V.

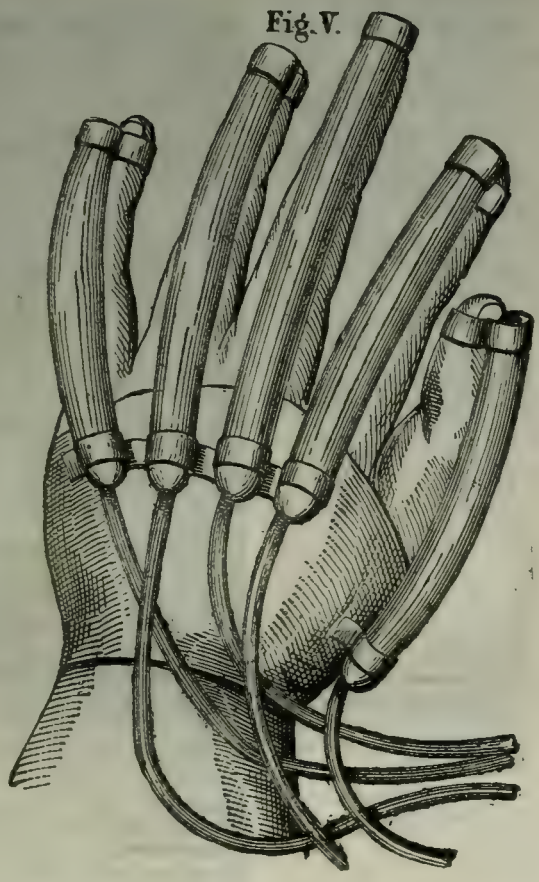


Fig. II

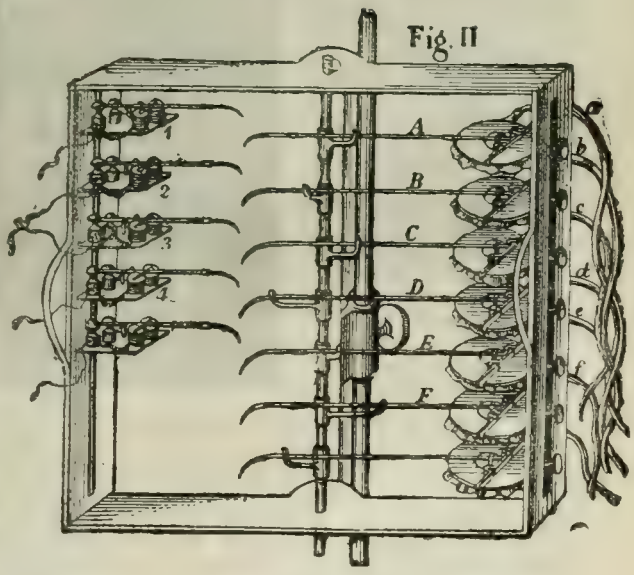


According to the postulates, each separate movement that can be performed independently, corresponds to a certain nerve-centre; each finger can be bent separately, hence each finger flexion shows the activity of the centre corresponding in time and degree. Separate finger movements show the activity of separate centres, coincident finger movements show the coincident activity of the several centres.

*

Tracing 1 shows the coincident tracings of five different digits. Each line corresponds to the movements of one tracing needle, the needle being moved by the bending of the finger tube with which the tambour of the needle is connected. Separate actions and coincident actions are indicated by the tracing. I have also arranged a mechanism which will enumerate on dials the separate actions and combinations of actions. (*See Journal of Physiology*, vol. iv., No. 2.)

2. Do we use many separate nerve-centres in a voluntary act? This may be experimentally shown by applying the motor tubes to the moving parts, thus obtaining lines corresponding to the movements of each part respectively, each finger, wrist, elbow, &c.

3. Is there a different physiological significance in the action of the centres governing the movements of large joints and small joints? The latter are often damaged by lesions that do not perceptibly interfere with the power over the large joints. In an experimental investigation we should note clinically the conditions and circumstances of the subject, while taking simultaneous tracings of movements in the different parts.

4. Is there any special significance in the action of the centres causing the movements of collateral parts, such as the fingers, specially considered as to whether they act coincidently or independently. (*See* "Brain," Oct., 1883.)

5. Which centres are the most automatic, *i.e.*, the most frequently seen in spontaneous action? We may take as the criterion of the automaticity of a nerve-centre, the frequency with which it acts spontaneously. The attempt must then be made to define what is meant by "spontaneous action." The term "spontaneous action" is used to imply that the muscular action is believed to be due to a stimulus originating in the nerve-centre, due to the intrinsic vital nutrition of the nerve-mechanism, not due to reflex action. Automatic actions are those due to the intrinsic nutrition of the nerve-centres, and are not reflex. In making observations to determine the frequency of some nerve-muscular movement that is apparently performed spontaneously, we may proceed thus :—

(*a*) Look at the subject, observe and note what nerve-muscular movements are most frequently repeated without any coincident stimulus from outside, and without the removal of any external inhibitory influence. Such observations may be made by the graphic method and process of enumeration.

(*b*) Observe the subject when in special conditions, such as sleep, when under the influence of chloroform, in coma from disease, and in other conditions in which it is known that the subject is less receptive to the effects of external influences, and note the relative frequency of certain nerve-muscular movements under these circumstances. As an example, in coma horizontal movements of the

eyes are more frequent than those in the vertical direction, and they may therefore be said to be the most spontaneous or automatic.

6. Observation may be made showing how spontaneous movements are modified or inhibited by external agencies.

TRACING 6 (p. 3), showing how the automatic or spontaneous movements of an infant were inhibited by a strong light.

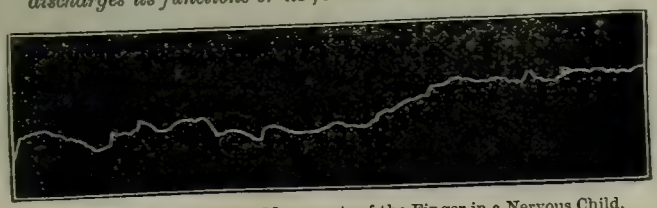
Spontaneous movements are the most numerous in kind, and the most frequent in infancy, less frequent in adult life. It seems probable that the spontaneous nerve-muscular movements in the adult are the remnants or survival of the spontaneous movements of infancy.

7. With the aid of the hypothesis of nerve-centres various problems may be stated, and the terms of each reduced to such form of expression, according to the hypothesis, as to enable us to submit it to direct observation and experiment.

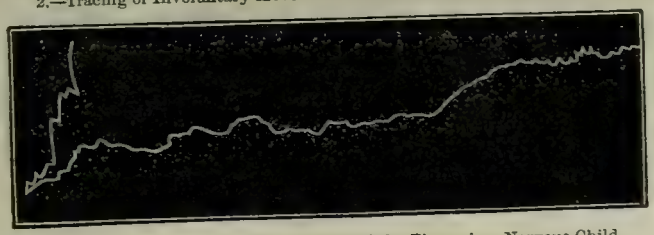
A part of the intrinsic vital history of a nerve-centre is indicated by the rhythm of the periods at which it discharges its functions or its force.

8. In the case of a motor nerve-centre, or a centre having motor function, we obtain a knowledge of this rhythm of its function by taking a graphic record of the nerve-muscular movement resulting. Histology by itself cannot demonstrate such properties. When the rhythm of the discharge of the motor function of a nerve-centre has been determined we may make another set of observations to try and determine whether its other functions follow a similar rhythm in the order of their discharge.

9. The varying conditions of a given motor-centre may be noted. Consider a special group of muscles, say, those elevating the angle of the mouth on the right side. The movements of these muscles are nerve-muscular signs of the action of the motor-centre, or centres corresponding. (TRACING 3.) The varying conditions of these nerve-muscular signs show the varying conditions of the nerve-centre. We may examine the condition of this centre in the subject under varying conditions, by comparing these nerve-muscular signs in chorea, hemiplegia, hemispasm, chronic tic, &c., in a patient under nitrous oxide gas, in awkward nervous people, &c. (TRACINGS 4 and 5.)

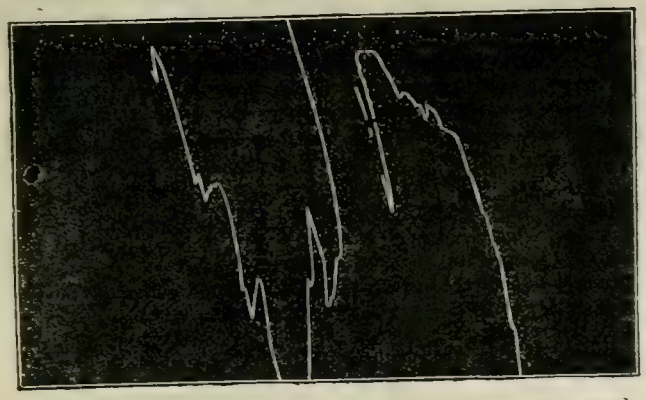


2.—Tracing of Involuntary Movements of the Finger in a Nervous Child.



3.—Tracing of Involuntary Movements of the Finger in a Nervous Child.

4.—Tracing of Finger Movements in Chorea.



5.—Finger-Tracings in Chorea. The twitching movements are compound.

Thus: In observing these special movements there may be—

(*a*) Variation in the spontaneous discharge of motor force at different times.

(*b*) From time to time there may be alteration in the rhythm of the movements, or loss of all rhythm, so that all that is observable is the frequency of the discharge of the centre in given periods of time.

(*c*) The nerve-centre may be active or inactive.

(*d*) Motion may vary as to its quantity.

(*e*) There may be a change in the function of a nerve-centre. In the development of a child its hand loses its spontaneous movements, but grows in mentation and intelligent voluntary power of manipulation.

(*f*) Is the centre liable to discharge by reflex action? This would be observed by noting the frequency of a special movement occurring coincidently with, or independently of, the action of a special external stimulus.

(*g*) Is the centre greatly under the influence of inhibition?

The Tracing 6 represents the movement of the finger of an infant five months old. Spontaneous muscular movements are occurring all over the body, and these are arrested or inhibited by the action of light and sounds.

Having referred to the vital history of a nerve-centre, we may consider some propositions concerning a group of centres.

We may study the action of a group of nerve-centres, and observe the action of each member of the group.

Take the group of centres which cause movements of the two upper extremities; this group for the upper extremities may easily be divided into two, one for either arm, each limb can move separately, therefore each of these sub-divisions can act separately.

Again, consider the group of centres for the right upper extremity, and it will be seen that the centres for the muscles of shoulder, elbow, and wrist, can act separately or in combinations. Further, und

circumstances the fingers move separately, at other times the centres for the muscles of all the fingers act synchronously or in combination.

Such observations as those here given, if made exactly and carefully, appear to demonstrate that in a group of nerve-centres we may have a separate action of each centre, or we may have certain combinations of nerve-centres acting synchronously. If in a given case we consider only a certain number of centres, we can have only a fixed certain number of possible combinations. If we consider n centres, the number of possible combinations in synchronous actions is represented by 2^n.

Again, the order of successions of the combinations of nerve-centres in synchronous action may be observed and recorded. There is no limit to the variations of order of successions or sequences, and no mathematical formulæ can express the successions.

ON THE NATURE OF SNAKE-POISON;

ITS EFFECTS ON LIVING CREATURES, AND THE PRESENT ASPECT OF TREATMENT OF THE POISONED.[1]

By SIR JOSEPH FAYRER, M.D., K.C.S.I.,

President of the Medical Society of London.

It was his purpose, Sir Joseph Fayrer said, to describe the nature and the mode of action of snake-poison in living creatures; and being most familiar with the Ophidia of India, he would select some illustrations from that source, especially as it afforded typical examples of snakes which were endowed with this terrible power of destroying life. The order Ophidia had three subdivisions: — 1. Ophidia Colubriformes (innocent). 2. Ophidia Colubriformes Venenosi. 3. Ophidia Viperiformes. The two latter were all poisonous—they were the Thanatophidia, and well merited this name in India, where they destroyed probably 20,000 human beings annually.

The general anatomical structure and distinctive characters of a snake were well known, but he would ask them to notice certain differences between:— 1. An innocuous and a poisonous snake. 2. Between a poisonous colubrine and viperine snake.

Snakes were provided with sharp re-curved teeth, which were fixed in the maxillary, palatine, and pterygoid bones; by the form and arrangement of these teeth, poisonous might be detected from innocent snakes. The harmless snake had two complete rows of ungrooved small teeth, one outer or maxillary, and one inner or palatine row; in the majority, there were from 20 to 25 teeth in the outer row. In the venomous snakes, the outer row was represented by one or more large tubular fangs, firmly ankylosed to the maxillary bone, which was movable, and, by its movement, caused the erection or reclination of the fang, so marked in viperidæ. In the innocent snake, the maxillary bone was elongated, and gave insertion to a row of teeth; in the poisonous colubrine, it was much shorter, giving insertion to only one or more teeth, the anterior and largest of which was the poison-fang. In the viperine snakes, the maxillary bone was reduced to a mere wedge, giving insertion to a long curved and tubular fang, which was a much more formidable weapon than the fang of the cobra, or other colubrine snake. These fangs, when reclined, were covered by a sheath of mucous membrane, in which lay also several loose reserve fangs, in different stages of growth. When the working fang was lost by accident, or was shed, one of the reserve fangs took its place, becoming fixed to the maxillary bone, and placed in communication with the duct of the poison-gland.

The teeth varied considerably in the different subdivisions of the order. They were described as being perforated. Though this was apparently the case, it was not really so. They were dense and compact, enclosing the usual pulp-cavity; but, being folded on themselves, formed either an open groove, as in the Hydrophidæ; a complete canal, as in the Cobra; or a more complete tube still, as in the Viperidæ. During development, the laminated tooth folded like a leaf on itself, and so formed the channel along which the virus was conveyed; and thus the tooth made a most complete hypodermic syringe. The poison was secreted by a conglobate racemose gland situated in the temporal region behind the eye. It was of considerable size, about that of an almond in the cobra, and was furnished with a duct which opened into the capsule of mucous membrane enveloping the base of the fang; the venom thence flowed into the dental canal, and was injected into the wound when the tooth penetrated the bitten object.

As there was good reason to believe that the total annual mortality from snake bites in India was not much, if at all, under 20,000 persons, or roughly about one in every 10,000, the subject was of much interest, and it was as important to humanity as to science to ascertain the nature and properties of the poison, and to discover what might best counteract it.

Snake poison was secreted by glands which represent the parotids in other creatures, and the virus was a transparent, slightly viscid fluid, faintly acid in reaction, and of varying specific gravity. When dried it lost from 50 to 75 per cent. of water, and formed a semi-crystalline substance like gum arabic. It was secreted in considerable quantities, and if a fresh and vigorous cobra were made to bite through a leaf stretched across a spoon or shell, several drops could be thus obtained. Examined under the microscope it was structureless. The poison was exhausted when the snake had bitten frequently, and it was then comparatively harmless; but it rapidly became dangerous again.

After a brief summary of the chemical analyses which have been made of snake poison, Sir Joseph Fayrer proceeded to discuss its effects in the living organism. "The symptoms caused by the venom of the different snakes," he said, "do not differ radically, save in degree, but there are symptoms which suggest that further investigation may bring to light certain differences by which it will be possible to discriminate one form of poisoning from the other. The activity of the venom differs not only in character and intensity in different genera and species, but also in the same individual under varying conditions of temperature, climate, health, and state of vigour or exhaustion at the time. It is a most virulent poison, and it takes effect when absorbed into the circulation, either by inoculation, or as I demonstrated in India (quite against all former and universal belief) when applied to a mucous or serous membrane, proving that it may neither be sucked from a bite, nor swallowed with impunity. It acts most rapidly on warm-blooded creatures, sometimes with lightning-like rapidity, when it enters a vein; it is deadly also to cold-blooded creatures, and to the lowest forms of invertebrate life. Strange to say, and this, to me, is one of the greatest of its mysteries, a snake cannot poison itself, or one of its own species, scarcely its own congeners, and only slightly any other genus of venomous snake, but it kills innocent snakes quickly. It has been ascertained that a vigorous cobra can kill several dogs, or from a dozen to twenty fowls, before its bite becomes impotent, and then the immunity is of brief duration, for the virus is rapidly reformed.

[1] Abstract of an address delivered at the Medical Society of London, Monday, January 28th, 1884.

"Snake poison is a neurotic, and kills by extinguishing the source of nerve energy. It is also a blood poison and an irritant; if applied to mucous and serous surfaces it causes inflammation; absorption then takes place, and the symptoms of general poisoning are induced. It causes great local disturbance, as well as blood change; for, if the bitten creature survive long enough, the areolar tissue may inflame, suppurate, and slough. If it enter by a large vein, life may be destroyed in a few seconds. It was supposed the more active poisons acted by shock through the nervous system; the rapidity with which a poison can be distributed through the circulation would account for the most rapid death from snake-bite. The chief effect is on the respiratory apparatus, and death occurs by asphyxia, but the whole voluntary muscular system is also affected, and general paralysis results; whilst the long continuation of cardiac pulsation after apparent death, proves that it is not due to failure of circulation.

"The action of snake-poison is discussed at full length in the *Proceedings of the Royal Society* by Dr. T. L. Brunton and myself (1872–74–75–78). These researches led us to conclude that the action of the poison is: 1, on the cerebral and spinal centres, especially the medulla, inducing general paralysis, especially of respiration; 2, in some cases (where the poison has been conveyed through a large vein directly to the heart by tetanic arrest of cardiac action, probably owing to action on the cardiac ganglia; 3, by a combination of these causes; 4, by blood-poisoning of a secondary character.

"The phenomena vary according to the nature of the snake, and the individual peculiarities of the creature injured, the chief difference being observed in viperine as contrasted with colubrine poison. The latter is a nerve-poison of great deadliness, but as a blood-poison it is not of much power. Viperine poison, on the other hand, is a more potent blood-poison. Dr. Wall summarises the difference in the action of daboia (viperine) or cobra (colubrine) poison as follows: 'Cobra poison, when introduced slowly into the circulation, produces gradual general paralysis, but at the same time shows a preference for certain nerve-centres; paralysis of the tongue, lips, and larynx being very marked symptoms, and respiration is very quickly extinguished after the paralysis shows itself. Death is often attended with convulsions, which are clearly due to carbonic acid poisoning. Introduced with a fair amount of rapidity, these symptoms are rapidly developed, the paralysis being preceded by gentle stimulation, which causes slight muscular twitchings. Injected in a large quantity into the circulation, the stimulation is so violent as to cause general convulsions, of which, however, the respiratory muscles have the chief share, and which are immediately followed by paralysis and death.

"'The local effects of the poison are partial paralysis of the bitten part, pain, infiltration, swelling, inflammation, and ecchymosis round the spot where the poison has been introduced, and sometimes in other and distant parts, and, if the animal survive for some hours, infiltration and incipient decomposition of the tissues and hæmorrhagic discharges. The general symptoms are depression, faintness, cold sweats, nausea, vomiting, exhaustion, lethargy, unconsciousness. Dogs vomit, and are profusely salivated. They present an appearance as if the hair were "staring." As the poisoning proceeds, paralysis appears in the limbs, and tends to creep over the whole body. Albuminuria (especially in viperine poisoning), hæmorrhagic discharges, relaxation of sphincters, exhaustion, lethargy, convulsions, precede death. In fowls the appearance is that of great drowsiness. The head falls forwards, rests on the point of the beak, and gradually the fowl, no longer able to support itself, rolls over on its side. There are frequent startings, as if of sudden awaking from the drowsy state, then convulsions and death. In cases where the quantity of poison injected is large, and it is at the same time very active (as in cobra), the bitten animal small and weak, or if it have entered a vein, death is almost instantaneous, as from shock. In such case, the cardiac ganglia are probably paralysed; at all events, the heart suddenly ceases to beat.'

"So far, no physiological antidote to snake virus is known, and when the full effect on the respiratory centres is produced, remedies are of little, if any, avail; albeit, when the poison has entered in smaller quantities, treatment may be of service on general principles. Viewing the apparent analogy between curare and snake poisoning, death in both being caused by paralysis of the respiratory apparatus, Dr. L. Brunton and I hoped that, by keeping up artificial respiration and supporting the body temperature, we might keep an animal poisoned by snake virus alive until elimination had taken place, and the result of some experiments justified the anticipation to some extent, for animals were kept alive for many hours, but succumbed at length when the artificial respiration was withdrawn.

"The first and most important indication," continued the lecturer, "is to prevent the poison entering into the circulation; to this all else is subsidiary. The rapidity with which this takes place depends a good deal on the part of the body bitten, and on its vascularity. When the poison enters a vein, if the bite be inflicted by a vigorous snake, the result is generally rapidly fatal. Experiments on animals show that bites inflicted on parts, even where large veins are not implicated, produced their effects so rapidly, that only immediate severance of the part, or complete constriction, prevented absorption. It is necessary, therefore, as quickly as possible, after a bite has been inflicted, to apply a ligature above it, and so tighten it as to completely arrest the circulation. As it happens in 94 per cent. of cases that the bite is inflicted on an extremity, this may frequently be accomplished; but, in parts where no ligature or elastic bandage or cord can be applied, proceed at once to excise the bitten part—this, indeed, should be done in all cases, whether ligatured or not—first, make an incision through the bite, and reflect the skin; expose the tissue wherever that is altered in colour, dissect it out, and be careful to remove every part it; then apply cautery or some escharotic, or the permanganate solution, taking care that it reaches as much as possible in every direction where the poison may have infiltrated. After this is done, the ligature may be relaxed; for, if the virus be destroyed, the danger of its entering the circulation is past. Should it have already entered, as is only too probable, all that can be done is to give stimulants, keep the patient warm, at rest, and, when the respiration begins to fail, use artificial respiration, and endeavour to keep him alive till the poison be eliminated.

"Suction, being unlikely to be of much avail, is practically useless to the patient, and dangerous to the operator, and it should neither be encouraged nor relied on. Insist on the importance of quiet and perfect rest; the temperature should be kept up; the respiration, if it begin to fail, supported by artificial methods. Where the poison has happily been limited to the seat of inoculation, and in cases where no great quantity of virus has been absorbed, we may hope to do good; but, where the poison has entered the circulation in larger quantities, and the physiological symptoms are developed, the prognosis is exceedingly unsatisfactory.

"In the latter case, if the patient become faint or depressed, unconscious, nauseated, or sick, and respiration begin to fail, with symptoms of paralysis of tongue and fauces, mustard poultices, or liq. ammoniæ on a cloth, should be applied on the stomach and heart;

stimulants should be given and the patient kept warm, but not shut up in a hot stifling room, or a small native hut; it is better to leave him in the fresh air than to do this."

Some remarks were next made on the remedial value of permanganate of potash. During his investigation of the value of remedies for snake poisoning, permanganate of potash was not omitted; and a number of experiments had been made; but the result was practically nil.

He agreed with Dr. Wall, "that potassium permanganate destroys the active agent of cobra-poison by oxidising it; but, when introduced into the blood, it of course commences oxidising indifferently all the organic matter with which it comes in contact; but it has no power of selecting one organic substance for oxidation rather than another. The oxidising power of the permanganate is, therefore, exerted on the constituents of the blood generally, instead of being reserved for the cobra poison in it alone; so if cobra poison is dissolved in an organic solution, and the permanganate is added before injection, the poison suffers little if any diminution in strength, for oxidation has taken place chiefly at the expense of the other organic matter. Thus, it would be necessary to destroy all the constituents of the blood by oxidation before all the poison in it could be destroyed too. If a substance should be found having the power of oxidation, with a special affinity of exercising it on snake poison, the problem of the treatment of snake bite would be solved; but potassium permanganate has not the special power."

After reading a letter from Dr. de Lacerda, of Rio de Janeiro, in which this point was discussed, Sir J. Fayrer made a very complimentary acknowledgment of the valuable labours of such Indian observers as Dr. Short, Dr. Nicholson, Dr. Stradling; of Drs. Grant, Richardson, and Wall, of Dr. Halford in Australia, Dr. Lacerda in Rio Janeiro, Dr. Lauder Brunton, F.R.S., and Drs. Weir Mitchell and Reichart, the last two of whom were engaged in the most important and much needed investigations into the chemistry of the poison and the condition of the blood and tissues of the poisoned.

He concluded by making a brief allusion to the case of Col. M., who, while serving in Zululand, was bitten in the leg by a venomous serpent, of which he died in ten hours, all remedies and care notwithstanding. The full details of this case will be found in the next Army Medical Department Report.

REPORTS OF
HOSPITAL PRACTICE IN MEDICINE AND SURGERY.

EAST LONDON HOSPITAL FOR CHILDREN.

CASE OF FATAL FÆCAL OBSTRUCTION.

(Under the care of Dr. EUSTACE SMITH.)

WILLIAM T. R., aged 8 years, was admitted into the hospital on the afternoon of January 4, nominally under Dr. Smith's care. Owing, however, to the boy's somewhat unexpectedly rapid death, he had not the advantage of being seen by Dr. Smith, and for the clinical details of the case we are indebted to Mr. Skete, one of the resident officers who was on duty in the hospital at the time of the patient's admission.

The previous history was as follows:—

His bowels have been inactive from infancy. He has always had a big belly, and has suffered from flatulence, and been accustomed to take purges.

He was an in-patient in the Bristol Children's Hospital in 1881 for seven weeks. While in the hospital his abdomen became smaller. His bowels were afterwards fairly regular for about a fortnight. He has never complained of pain, and was much relieved by passing wind.

The family history is good. His parents have one other child. About the 1st of January this year, his mother noticed his stomach getting larger, and he was brought to the hospital on this account. On admission, his bowels were said not to have acted for a week, the motion then being very small and dark.

After his admission to the hospital, he seemed very thirsty, and constantly asked for milk, which he returned immediately, putting his fingers into his pharynx to induce vomiting. His abdomen during the evening became more swollen, and his feet very cold.

In view of the apparent chronicity of the disease, no immediate danger was anticipated. The boy, however, became very restless about 11.30 p.m., and when in the act of swallowing a sleeping draught of bromide of potassium and hyoscyamus he quietly died. There was no fæcal odour about the vomited matters.

Autopsy:—At the *post-mortem* examination, made by Mr. R. W. Parker, with the assistance of Mr. Arthur Maude, and in the presence of Dr. Donkin and some visitors, the body was found to be well nourished. The abdomen was enormously distended. The lower limbs were somewhat œdematous, especially the left. On opening the body in the usual manner, and after removal of the sternum, the highest point of the diaphragm was found to correspond with the third intercostal space. The heart was very much flattened on its posterior aspect, doubtless between the diaphragm and the chest-wall; its right side quite empty. The lungs were healthy; a small quantity of serum was found in each pleural cavity. In the abdomen was contained a small quantity of slightly turbid serum. The small intestine, which was quite empty, and in all respects healthy-looking, was completely hidden from view by coils of the large intestine, which were enormously distended. Occupying a considerable portion of the central part of the distended abdomen, was the sigmoid flexure; reference to the drawing (at A.B.) will make its size and relative

position more easily understood; at the spot marked with an arrow, its semi-diameter measured 9 inches; at A, a stone-like mass of solid fæces was found, and this was the cause of the obstruction. At B, the gut curved backwards rather sharply, and then passed through the left lumbar region as the descending colon. C is a portion of the transverse colon, which is much distended, and apparently elongated. It passes beneath B, obliquely from left to right, to the hepatic flexure of the colon, which it joins. Along its centre, the unaltered great omentum is attached; the stomach is greatly dragged upon, contracted, and quite empty. At A, the bowel passed into the pelvis and, resuming its normal size, became the rectum. It would seem as if, owing to its being bound down by a very short meso-rectum, the rectum as it dipped down into the pelvis formed

an acute angle with the part marked A : the hard mass of fæces above mentioned was thus quite unable to pass, and hence the fatal obstruction. All the coats of the large intestine were much hypertrophied ; the peritoneum also was greatly thickened, and could be peeled off in considerable layers : its surface, however, was nowhere split ; the longitudinal bands were especially thickened. The shaded spot (in the woodcut) between A and B was thickened peritoneum, and it bound these parts of the gut firmly to each other.

The large intestine was filled with dark olive-green thickly-liquid fæces, of which not less than half a bucketful was removed. The intestine was then well washed out, and its interior surface examined : beyond a little congestion, it presented no abnormality. The solid mass of fæces, described as at A, was of the same colour but, being drier, of a somewhat darker shade : this mass was of the consistence of sun-dried clay, and considerable force was required to break it up : it was of the size of a double adult fist ; when broken up, it presented a very scintillating appearance, owing to the large amount of crystalline matters which it contained. The odour, though characteristic, was very mild.

The kidneys, liver, and spleen were all normal. The psoas muscles were both very much atrophied.

The sketch from which this woodcut is taken was made by Mr. Maude, and faithfully represents the relative position and size of the intestinal coils.

Remarks :—Such extensive cases of fæcal accumulation (sterco-enterectasis or coprostasis, to call them by their proper names) as the present one are very uncommon, and fortunately fatal cases belong to the greatest rarities. The absence, in this case, of those graver symptoms which accompany acute obstruction, was very noticeable ; this, coupled with the faulty history, and the very lengthened period over which the constipation had lasted—it was practically from birth—renders it hardly surprising that the child's death was unlooked for by the medical officer in charge of the case, or that the cause of death, fæcal impaction, was quite unsuspected. The greatly-distended condition of the large intestine, the hypertrophy of its walls, the healthy condition of its mucous membrane, the absence of all constriction below the seat of the impacted fæces, and the fatal termination, are the chief points of interest. The fæcal mass did not present any nucleus (plum stone, foreign bodies, or even enteroliths) around which fæces had collected, such as is found in many cases of this kind, but it contained a considerable quantity of "intestinal sand" to which doubtless the glistening aspect before alluded to was due. In adults, the habitual use of narcotics, the presence of tumours in the pelvis, pregnancy, wearing of pessaries, are sometimes found to give rise to fæcal accumulation and obstruction ; but in the present case no physical cause could be assigned. Some authorities believe such habitual constipation to be due to deficient production of the intestinal juices : the mucous membrane was not examined microscopically, and it is therefore impossible to say whether any congenital peculiarity of its secreting gland structure existed in this case ; the fæces found in the large intestine were in the form of a thick liquid, and would thus favour such a view.

The absence of peri-typhlitic inflammation was perhaps not very strange, seeing that the stress of the disease lay in the sigmoid flexure ; on the other hand, the absence of all ulceration within the colon is a little remarkable. Next to the rectum, fæcal accumulation in this position is the most accessible to surgical treatment, as being within the reach of a scoop, or of an enema ; differing in these respects from accumulation in the caput coli, where it is both inaccessible, and so to speak, outside the ordinary fæcal current, by which it might be swept onwards.

Medical Times and Gazette.

SATURDAY, FEBRUARY 2, 1884.

A LETTER just received from Professor Panum, the President, gives some interesting details of the arrangements in progress for the meeting of the International Medical Congress to be held in Copenhagen on August 10th. In June of last year a provisional programme of the business to be transacted in each of the different sections was sent to the principal medical men in each country interested in the various subjects. Many valuable communications have been promised in consequence, and nearly 400 non-Scandinavian colleagues have already announced their intention to attend. From France, amongst others, come Pasteur, Paul Bert, Ranvier, Charcot, Verneuil, Cornil, Hayem, Malassez, Chauveau, Ollier, Tripier, Lepine. From Italy—Biszosero, Mossa, Galgi, Peromento, Novaro, Reymond, Giacomo, Baccelli, Tomasi-Crudeli. From Holland—Donders, Guye, Engelmann, Heinsius. From Germany—Virchow, Ludwig, Esmarch, Volkmann, His, Braune, Kronecker, Munk, Kühne, Heidenhain, Vogt, Bernstein, Grohe. The most eminent medical men of Sweden and Norway have become members of the various committees of organisation ; so that the Congress, at the instance of the President himself, will possess a truly Scandinavian character, and the medical men of Sweden and Norway will attend in as large numbers as if the congress were their own.

Professor PANUM trusts that a large number of English medical men will be present, the more so as English is one of the official languages. The Danish Parliament and the City of Copenhagen are taking an active interest in the success of the meeting ; and "We shall not be ashamed," Professor Panum adds, "of being compared with previous congresses, always excepting the Congress of London, whose prodigality we certainly shall not have the presumption to imitate. The King and Crown Prince evince great interest in the success of the meeting, but we do not intend to mention in our programme any festivities, solemnities, and such like ; we would rather emphasize our intention to make the congress a meeting for strictly professional and scientific work."

ON Monday evening, at the Medical Society, Sir Joseph Fayrer gave an admirable address on snake poison, which we give in abstract elsewhere. There was a very full attendance, including many well known in the Army Medical Department. The case of Col. M., who, while serving in Zululand, was bitten in the leg, and notwithstanding all that could be done for him, died within ten hours of the accident, served as the not inappropriate text. And if we further remember that probably not less than 20,000 persons annually die of snake bite in India, it will be conceded that such an address as that given by Sir Joseph Fayrer, practical in every detail, and from one conversant

with every side of the question, could hardly fail to excite great interest even in a country so happily free from venomous snakes as our own. The anatomy of the various venomous and non-venomous snakes was described and contrasted, and the peculiar apparatus by which the venomous snakes poison their victims was accurately described, and illustrated both by specimens and drawings. The peculiar poison fang was not inaptly described as a fine hypodermic syringe, and it was shown how the celerity of the action of the poison might depend on various causes —the spot might be very vascular, or the reverse; or a vein might be directly punctured, a misfortune which always rapidly hastened the fatal result; or the poison itself might vary in intensity according to the activity and strength of the snake. The inutility of permanganate of potash was referred to; in a test tube it was infallible, but when once the venom was absorbed into the blood it was utterly useless, since it possessed no power of selecting the poison, but acted alike on the blood and all its constituents. The only safety lay in preventing the absorption of the poison.

The meeting of the Clinical Society on Friday, January 25th, may be said, in the language of the Bourse, to have "opened flat." Possibly the somewhat diminished attendance of members may be attributed to a natural reaction after the vigorous debates of the earlier part of the session. Two papers of considerable surgical interest were communicated by Mr. Rivington, on "An Unusual Form of Dislocation of the Hip"; and on "Temporary Ligature of the Carotid Trunk for Recurrent Hæmorrhage." Neither of these papers, however, succeeded in eliciting either comment or criticism. A paper by Dr. Donald Hood, on "Angina Pectoris followed by Pericarditis," formed the text for a discussion upon cardiac neuralgia, which brought out many points of interest. A case of "Empyema followed by Abscess of the Brain" was related and commented upon by Dr. de Havilland Hall, and from the subsequent debate, which turned chiefly on the surgical treatment of empyema, it would appear that the operation of excision of portions of ribs is rapidly gaining favour amongst surgeons. An interesting case of deliberate self-starvation, due to melancholia, in a young girl of 13, was shown by Dr. Heron. A case of Hygroma of the Arm, undergoing spontaneous cure, was also exhibited.

Death from empyema, that is to say, death from the consequences of pent up pus in the pleural cavity, ought to be regarded as an opprobrium to the practitioner under whose supervision it takes place. Of all morbid conditions affecting the chest there is none which admits of such certain diagnosis, by the application of certain hard and fast rules, as that of fluid effusion into the pleural cavity. Nor is there any better-established rule of practice than that, when the effusion has been clearly proved to be purulent, it should be evacuated. Perfect evacuation usually fails from one of two causes. Either because the opening is not made large enough, or because it is made in the wrong place. All the speakers at the Clinical Society's meeting, and indeed all writers on the subject, have agreed that if a hole has to be made in the chest wall it is a matter of indifference whether that hole be a large or a small one. To determine the right place to make it, we can be guided by no other rules than those supplied by a knowledge of anatomy and physiology, aided by a common sense interpretation of physicial signs; but, if an opening in one part of the chest has failed to effect its object, and smaller or greater collections of pus are still to be found accumulating, it appears to us that a further and more complete system of drainage is as imperative as was the evacuation of the larger collection in the first instance. The spectacle of a case dragging on a weary suppurative existence for many months is a most melancholy one, and it is unfortunately by no means rare.

At a recent meeting of the New York Pathological Society, a specimen was exhibited by Dr. Robinson, consisting of a heart from an individual 6 feet 4 inches tall, and of corresponding proportions, who had suffered for years from symptoms of disturbed circulation. The organ weighed 55 oz., and was believed by Dr. Robinson to be the largest on record. The president, however, cited one formerly presented to the Society by Dr. Clark, which weighed 57 oz.

Mr. George Roper will deliver the Annual Oration of the Hunterian Society, in the theatre of the London Institution, on Wednesday, the 13th inst., at 8 o'clock.

Surgeon-General Hunter's long expected report on the cholera epidemic in Egypt has at last appeared, together with two volumes of correspondence on the same subject. The papers have come into our hands too late to do more this week than merely chronicle the fact of their publication. The report itself only occupies some eighteen foolscap pages, but it is crammed with facts and will repay careful study. The greater part of the evidence on which Dr. Hunter bases his conclusions is already known to the profession, his paper read before the Epidemiological Society being little more than his report in another form. The report, however, contains in addition a careful summary of recent researches into the ætiology of cholera. Of Koch's discovery, Dr. Hunter says, "I believe the bacilli discovered by Dr. Koch in the intestinal canal of persons who have died of cholera, are the result of decomposition, and that the evidence of this is to be found in the report itself. It must also not be lost sight of, that although some of the necropsies were conducted immediately after death, yet there is a microscopic death during the algide stage of cholera, which is antecedent to 'real death,' the cadaveric odour often being perceptible during life."

In a letter to Dr. Hunter, date Jan. 15th, 1884, Lord Edmund Fitzmaurice expresses Lord Granville's satisfaction "at the energetic manner in which you executed your mission, and his appreciation of the great attention which you gave to the nature of the cholera epidemic and to all sanitary questions in Egypt, as well as the valuable information contained in the able and complete reports which you have furnished on the subject. Lord

Granville does not doubt that these papers will contribute materially to the scientific knowledge of the character of the disease, and will claim a careful perusal by all those who take an interest in this important subject."

Professor Parker will commence his course of nine lectures, "On Mammalian Descent," in the theatre of the Royal College of Surgeons, on Monday next, the 4th instant; he will deliver them on Mondays, Wednesdays, and Fridays, at 4 o'clock, and will be succeeded by Professor Flower on the 25th instant.

The inaugural meeting of the Hospitals Association will be held at the Mansion House to-day (Friday), at three o'clock, under the presidency of the Lord Mayor, when the speakers will include Earl Stanhope, Lord Frederick FitzRoy, Sir T. Fowell Buxton, Sir Rutherford Alcock, Mr. Timothy Holmes, and others. It may be as well to remind our readers that the objects of the Association are—(1) To facilitate the consideration and discussion of matters connected with hospital management, and, where advisable, to take measures to further the decisions arrived at; and (2) to afford opportunities for the acquisition of a knowledge of hospital administration, both lay and medical. The association will afford facilities for the reading, discussion, and publication of approved papers; for the delivery of lectures, and for the holding of conferences on hospital administration, hospital management, medical relief, medical education in relation to hospitals, free and provident dispensaries, and other kindred subjects; and will found a library, consisting of works on hospital administration, construction, finance, and statistics. The association is to consist of members and associates, who will subscribe respectively one guinea and ten shillings and sixpence annually. Both members and associates will be entitled to attend and vote at all meetings of the association, but members only will receive gratuitously the published papers or journals of the association and be entitled to the use of its library. A strong provisional committee, it will be remembered, was elected some time back, and the constitution of the association has been drawn up. The object of the Mansion House meeting is to formally establish the association, to ratify its constitution, and to submit the election of its council to the provisional committee. If wisely conducted the association may, no doubt, do much to evolve some order out of the present chaos.

The University of Cambridge have just issued in a pamphlet of convenient form, bound in linen, the regulations and schedules for medical and surgical degrees. This is a great improvement on the old schedules of foolscap size, which were very apt to get lost in transit between Cambridge and London, and could only be replaced by an appeal to the dissecting room porter. As regards the regulations and examinations themselves, these have undergone considerable changes during the last few years; for instance, botany has been merged into elementary biology with comparative anatomy, a move which is decidedly a good one, but we regret to see that the examination may be passed now in two separate parts. This tendency to subdivision is indeed shown in each of the examinations, and we are by no means certain that it is in all respects advantageous. If the examination extends over too large an area, by all means let it be split up, but why such an unequal division of labour as that which obtains in the second M.B. examination, where pharmacy and pharmaceutical chemistry form one part, and human anatomy and physiology the other part. In filling up his schedule for the third M.B., we fancy the candidate will, in most instances, have to commit a "pious fraud," and make the course of lectures which appeared as on "pharmacy and pharmaceutical chemistry," for his second M.B., now do duty as one on "physiological actions and therapeutic uses of remedies;" however, if the lecturer has no scruples, and they have not usually, at least not if the fees have been paid, the candidate may be well excused if he pockets his.

Some months ago we had occasion to notice the unsatisfactory position, from a financial point of view, occupied by the Downing Professor of Medicine in the University of Cambridge, and to record a futile attempt on his part to improve that position. We are glad to learn, from a letter addressed by Dr. Latham to the members of the Senate on January 22nd ult., that a Report of the General Board of Studies has been adopted, containing the following clause:—"That, provided the present Downing Professor of Medicine undertakes to comply with the provisions of Statute B, ch. xi, there be paid to him annually from the chest such sum, if any, as may be necessary to raise his whole stipend to an amount greater by £200 than the share of the revenue of Downing College paid to each fellow of the college." It will be in the recollection of our readers that Dr. Latham, in his original application to the Vice-Chancellor, only asked that the deficiency in his stipend, which for the three previous years had amounted to nearly £200 a year, should be made good in future years, so as to raise his emoluments to £400 a year in all, which was the value of the professorship when he was appointed. This is what the Senate have now practically granted—a tardy concession, it is true, but still, better late than never.

The series of four cases of Nephritis following Varicella, lately put on record by Professor Henoch, and mentioned in our last issue, must be received as a notable exception, proving the almost invariable rul that Chicken-pox runs its course without definite sequelæ. It cannot fail to be observed, however, that in every-day practice cases are constantly occurring in which there appears to be some influence at work to prevent the return of the patient to robust health. Without any definite symptoms of disorder, children frequently remain delicate and "out of sorts" for a considerable time after the disappearance of the rash. This period of weakness and unaccountable ill-health has often been mentioned by writers, and finds a place in more than one standard text-book; but it has come to be looked upon as a clinical fact, without any serious attempt being made to explain it. The possibility of

some slight renal disturbance must not be disregarded, now that a clear connection has been shown to subsist between Varicella and Nephritis.

The late unfortunate accident to the Marquis of Hertford terminated fatally on Friday, Jan. 25th, the fall having taken place on the 21st. Four days thus intervened, the injuries being of such a serious character that death might reasonably have been expected at a much earlier date. Not only was there grave concussion of the brain, causing a semi-unconscious condition from the first, but the spinal column and cord were also so bruised and crushed, in the lower dorsal and lumbar regions, that paraplegia rapidly supervened. To the spread of this paralysis, and to the exhaustion and shock consequent upon such extensive injuries, the Marquis (a man of seventy-two years, though naturally robust, and in good health at the time of the accident) could not but succumb. That he survived the disaster so long as he did was due mainly to the watchful and unremitting supervision of his medical attendants, who exhausted every resource of surgical science in the endeavour to prolong life.

It is noteworthy that this lamentable accident could not fairly be ascribed to the dangers of the hunting-field. The fox was scarcely on foot, and the chase not begun. It was on level ground, not in negotiating a fence, however small, that the fall took place. It may perhaps be fairly said that men of seventy-two years of age should not court the perils of the hunting field, since they must probably have lost both the nerve and the elasticity which enable a younger man to roll clear, if his horse is in difficulties. But if such a moral be drawn from this case, it must be extended to every form of horse exercise—since the accident to the Marquis of Hertford might have befallen him, in the same manner, on the level sweep of Rotten Row as on the Warwickshire grass.

It is stated by Lord Yarmouth that the horse ridden by his father on the day named, was not vicious, but that it was itself taken with a fit, or paralytic seizure, causing it to fall heavily forwards, then to roll on its side, crushing and kicking its rider, and to lie for half an hour afterwards on the ground, as if dead. If this be so, it seems probable that an attack of epilepsy, or "staggers," in the horse was the prime cause of the disaster.

The *New York Miller's Journal* contains some interesting facts, regarding the influence of temperature on the consumption of flour. We all know, though the mildness of the present winter has laid less emphasis on the fact than usual, that a greater quantity of heat-producing, and notably of farinaceous material, is required for the due preservation of animal heat and weight, in a low than in a high or mild temperature. The effect of cold, says the journal referred to, is, in England, to induce an extra consumption of wheat flour—while in the United States and in France *less* wheat is consumed in winter than in summer. The reason of this is that, in the latter countries, the need of extra farinaceous food is met by use of buck-wheat, Indian corn, and other grains, which are found to be both palatable and nutritious. In England, even the poorest people will starve rather than use any but the whitest of wheat flour, regarding all cheaper substitutes, and even the "whole meal" so strongly recommended, with suspicion and distaste. This is a pity, and should be amended; but the influence of habit is so strong, that at present the poor in our large cities will prefer even an inferior and adulterated wheaten flour to a more nourishing meal of other or mixed grain. They might be heavier and warmer, did they only believe it, both in pocket and in physique, if they would take a hint from the winter diet of their Transatlantic cousins.

Why is it that that most economical and nourishing of all foods—*oatmeal porridge served with milk*—finds, in spite of all that medical precept can teach, and medical example endorse, so few advocates in this country? Children who have been brought up to make it their daily breakfast, take to it naturally and easily, and thrive under its use. No hard-working adult who has proved its powers of support through a long morning of cold, exposure, and hard exercise, will allow that any other kind of food is so sustaining and so easily assimilated. Yet how rarely does it form a feature of our national breakfast table! This is chiefly, we believe, because few know how it should be prepared, in its perfection, so as to be both attractive and digestible.

The new edition of "Men of the Time" appears to have given satisfaction to nobody, except perhaps to the many inconsiderable persons whose appearance in it will surprise every one except themselves. The selection of "medical men of the time" appears to have been made as carelessly and as unwisely as that complained of in respect to several other professions, and it is much to be regretted that the editor did not consult some prudent and conscientious medical authority as to who should be admitted to his list of honour. As it is, many will be inclined to conclude that it is more distinguished not to appear in "Men of the Time;" for of some who are admitted into the volume it may be said without sarcasm that they are fitly called Men of this particular Time, for it is very certain that their names will be entirely strangers to any other.

The following is an alphabetical list of the members of the medical profession who appear in the volume:—Dr. H. W. Acland, Mr. William Adams, Sir Rutherford Alcock, Dr. G. J. Allman, Mrs. Garrett Anderson, Mr. Thomas Annandale, Sir Alexander Armstrong, Mr. J. M. Arnott, Dr. J. H. Balfour, Dr. H. C. Bastian, Dr. L. S. Beale, Dr. John Beddoe, Dr. J. H. Bennet, Sir Risdon Bennett, Professor Bentley, M. Paul Bert, Sir G. Birdwood, Mrs. Elizabeth Blackwell, Dr. Bodichon of Algiers, Dr. Bouchardat, Sir W. Bowman, M. Browne-Sequard, Sir G. Burrows, Dr. Alfred Carpenter, Sir Andrew Clark, Sir Oscar Clayton,

Dr. T. S. Cobbold, Dr. Collingwood, Surgeon-General Crawford, Mr. T. B. Curling, Dr. Dalton of New York, Dr. W. H. Dickinson, Prof. Du Bois-Reymond, Dr. Matthews Duncan, Dr. Milne Edwards, Dr. Arthur Farre, Sir Joseph Fayrer, Dr. Austin Flint, Prof. Flower, Deputy Inspector-General Giraud, Dr. Asa Gray of Harvard, Dr. S. Gross of Philadelphia, Sir W. Gull, Dr. Günther, Dr. W. A. Guy, Mr. Seymour Haden, Dr. W. A. Hammond, Deputy Surgeon-General Hanbury, Dr. G. Harley, Mr. Ernest Hart, Mr. Christopher Heath, Prof. Helmholtz, Sir Prescott Hewett, Prof. Hofmann of Berlin, Dr. Wendell Holmes, Sir J. D. Hooker, Mr. Jonathan Hutchinson, Dr. T. J. Hutchinson, Prof. Huxley, Sir W. Jenner, Dr. G. Johnson, Dr. G. Johnston of Dublin, Mr. Wharton Jones, Sir John Kirk, Prof. Koch, Dr. R. G. Latham, Dr. J. Le Conte, Dr. J. Leidy of Philadelphia, Sir W. MacCormac, Dr. Mapother, Dr. Alexander Marsden, Mr. Francis Mason, Dr. Maxwell Masters, Dr. Alfred Meadows, Dr. W. Munk, Prof. Alleyne Nicholson, Professor Odling, Sir R. Owen, Dr. Paget, Sir J. Paget, Prof. Pasteur, Dr. John Percy, Dr. Pell Pettigrew, Dr. W. O. Priestley, Dr. Richard Prior, Dr. B. W. Richardson, Prof. Burdon Sanderson, Mr. John Simon, Dr. Grainger Stewart, Dr. Allen Thomson, Prof. Virchow, Prof. Vogt, Mr. J. H. Walsh (editor of the *Field*), Dr. W. H. Walshe, Mr. J. A. Wanklyn, Sir Spencer Wells, Dr. Samuel Wilks, and Sir Erasmus Wilson.

A GLANCE at the above list will suffice to show that there is not a branch of medical science in which some of the foremost men are not omitted. What can we think of a volume which, amongst well-known surgeons, forgets to include Sir Joseph Lister, Professor Marshall, and Mr. Savory; amongst physiologists, Dr. W. B. Carpenter and Dr. Michael Foster; amongst physicians, Dr. Quain, Dr. Garrod, Dr. Wilson Fox, Dr. Russell Reynolds, Dr. Pavy, Dr. Habershon, and Dr. Bristowe; and amongst obstetricians, Dr. Charles West, Dr. Robert Barnes, and Dr. W. S. Playfair. Amongst foreigners, the sins of omission are, if possible, more striking. There is no mention of Charcot, or Donders, or Erb, or Billroth, or Ziemssen, or of a score of others whose names rise to the tongue when we think of foreign leaders in medicine. It would be worth some one's while to issue a supplement to this play in which so many of the chief players are left out.

THE health of the whole country continues almost phenomenally good. During the last week the death-rate of twenty-eight large English towns was only 20·3, and of eight large Scottish towns 20·1. In the latter the number of deaths, 485, was just three-quarters of the number in the corresponding week of last year. Of the twenty-eight large English towns as many as nineteen had a death-rate of less than 20, a most unusual proportion. Norwich, which has a way of jumping from the top to the bottom of the class, and again from the bottom to the top, heads the list with a death-rate of 15·0, and Manchester ends the list with one of 26·8. The death-rate in Leeds, which comes last but one on the list, was sent up by an unusual mortality from scarlet fever. Of 97 deaths from this disease which occurred in the twenty-eight towns, 23, or nearly one-fourth, were registered in Leeds.

THE metropolis itself has had a very healthy month, the death-rate for the first four weeks of the year averaging only 20·4, against 24·4 and 20·9 in the corresponding periods of 1882 and 1883. During last week the death-rate was only 19·9, and the deaths were nearly 400 below the ten years' average. The deaths from zymotic diseases were 55, and those from respiratory diseases 179 below the corrected average weekly number. The most fatal zymotic affections were scarlet fever, measles, and whooping-cough, which caused respectively 32, 42, and 80 deaths. Diphtheria, too, was much more prevalent and fatal than it ought to be.

THE population of this metropolis is considerably less than the aggregate population of the other twenty-seven towns with which the Registrar-General deals, and yet there were sixteen deaths from diphtheria in London to ten in all the other towns, while of the 130 deaths from whooping-cough in the twenty-eight towns, eighty occurred in the metropolis, that is, considerably more than its proper share. Few people realize the enormous sacrifice of infant life brought about by whooping-cough, most of which could probably be avoided by proper care. Scarcely a week passes but some new hospital is proposed, but no one, so far as we are aware, has ever advocated the formation of hospitals for whooping-cough. And yet half-a-dozen compact little hospitals for this complaint, scattered over the metropolis, would probably save more lives than an equal number of pretentious buildings devoted to special cases which would be much more in place either at home or in the general hospitals. The equable temperature required for the successful treatment of whooping-cough can only be secured in a hospital ward.

LOGICIANS have often puzzled their brains for a concise definition of man which would satisfactorily differentiate him from animals. The propositions that "Man is a cooking animal," and that "Man is a clothes-wearing animal," have been successively suggested and rejected, for however true it may be that no animal but man is versed either in the mysteries of the kitchen or the toilet, it is not equally true that all men use those adjuncts of civilization. Perhaps the proposition that "Man is a drug-loving animal" might be accepted where these other statements have been found wanting; at any rate it is a proposition from which the late Mr. Holloway worked out a very satisfactory syllogism. That it is true of civilized man we all know, and we have the veracious testimony of countless travellers to the effect that it is equally true of man uncivilized. This is what the latest of them, Mr. F. L. James, says of the wild tribes of the Soudan: "Nothing gives an African savage greater pleasure than a good dose of medicine; but it must be a strong one and rapid in its effects. A good dose of croton oil and colocynth, or four or five grains of tartar emetic, is what they like. . . . . At some places, Cassala for instance, there were days when as many as 200 people

visited the doctor, who gave away, among other drugs, great quantities of Holloway's pills. These pills we found immensely popular, and we took a good supply with us, in half-pound boxes, on each of our expeditions." After all, among the many resources of civilization, even croton oil may be considered as on the whole less deleterious than rum.

THE half-yearly examination for commissions in the Army Medical and East India Medical services will be held at Burlington House on Monday next. The number of vacancies in the former is stated to be twenty, and in the latter five, and to fill these we believe it will be found that an ample number of candidates will present themselves. The wisdom of the policy adopted by the governing authorities in making the services popular with the profession has been thoroughly illustrated at these recent examinations, and they have become, what they certainly were not in former days, genuinely competitive. With satisfactory results, such as these, achieved, it should not be for us to moot any point likely to mar the general contentment; but, nevertheless, we must be permitted to express our regret that at present there appears no prospect of finding the army medical officer placed upon the same footing as regards "honours and awards" during active service, as his brother combatant officers. This invidious distinction is a relic of ancient times—one of those old customs which has not been changed to meet the altered condition of things. The new era of rifled projectiles and long-carrying guns unquestionably makes those medical officers who have to be well up in the rear of the fighting line, combatant officers, and necessitates their approaching very considerable danger without the stimulus of excitement enjoyed by the regimental officer. That this view of things is not imaginary, the records of our recent little wars abundantly prove, since "killed in action" has had to be written after the name of many a medical officer, and, whatever amount of opposition the idea may evoke, we shall certainly continue to express a hope that at no very distant day this manifest injustice will be remedied.

THERE are not many points in which we are willing to admit that the Germans are superior to ourselves; but they have one characteristic which is in the highest degree worthy of our envy and imitation, and that is their reverence for the work and conclusions of experts. Here in England everyone has an opinion on every subject, and thinks himself as much entitled to hold it against all comers as though he had given a life time to its formation. The assurance with which such flimsy views are expressed—whether the subject be science, art, or politics—is simply laughable to the expert, who knows only too well how reliable conclusions are formed, and would make an average German's hair stand on an end. In Germany they order this matter better, and a striking example of it has just been reported in connection with vivisection. During the last session of the German Parliament, the anti-vivisection party raised the question whether vivisection should not be prohibited in educational establishments and its abuse punished by law. The minister referred the subject to the medical faculties, and the verdict of the committee of the Berlin University, composed of some of the ablest and best-known medical authorities in Germany, was published last week. It maintains that vivisection is essential for the study of physiology, further progress in which would be impossible without it, and that no definite judgment can be formed by students if they have not been taught by experiments the most important laws of life. There we suppose the matter will practically end. There will no doubt be another debate on the subject, but the Germans will belie their well-known character if they venture to legislate in the face of this definite expression of opinion by their best experts.

A QUESTION of more than local importance is raised by a decree promulgated in the Grand Duchy of Baden, by which a Board of Control is to be appointed to exercise supervision over the conduct of medical practitioners within the jurisdiction of that State. The Board is to consist of five medical members, with one government official, sitting as assessor, and its functions will apparently be to guard the honour of the profession from abuse or evil repute, by proceeding against, or degrading, such of the members of it as have been guilty of malpractice or unworthy conduct. This form of State interference in medical affairs met with active criticism at a meeting of the Berliner Medicinische Gesellschaft on the 23rd of January, the debate being ultimately postponed until the next meeting of the society. A decided difference of opinion found expression in the various speeches delivered; but the importance of the discussion was fully endorsed by Professor Virchow, who pointed out the probability that further legislation on medical matters is imminent, both in the Landtag and the Reichstag, and that this new decree of the Baden Government, if left unchallenged, would unquestionably be taken as a standpoint for further action in a similar direction.

THE profession in Vienna has received with the highest satisfaction the announcement that the Emperor has conferred upon Dr. Carl Stellwag v. Carion, Professor of Ophthalmalogy, and Dr. Joseph Späth, Professor of Clinical Gynæcology, the title of Hofrath, in recognition of the great and prolonged services which they have rendered to the Vienna Medical School.

A COMPANY is being started for the establishment of a sanatorium on the south coast of the Isle of Wight, close to the well known Black Gang Chine. It is proposed to purchase for this purpose the house in which the late Dr. Pusey used to live, and which those who know the part will remember far down below the level of the high road and close to the sea. It will be admitted that a better site for a sanatorium could hardly have been selected. It is well protected from the north and east, without having the oppressive climate of the Undercliff. It overlooks a fine expanse of sea, and the only disadvantage is that one has to cross the Solent to get there. The capital of the company is to be 20,000*l.*, in 4,000 shares, and shareholders

are to enjoy special advantages if they elect to stay at the sanatorium. Similar establishments in other parts of the country pay good dividends, and we see no reason why this new medical hotel should not be equally successful. If it is well managed it ought to benefit both its shareholders and its supporters.

A LARGE meeting of medical and other members of the University of Aberdeen was held on January 23rd at the Inns of Court Hotel, under the presidency of Sir Andrew Clark, Bart., M.D., to consider a proposal to found an Aberdeen University Club in London. The proposition was received with enthusiasm, and it was announced that the Duke of Richmond and Gordon, K.G., Chancellor of the University, had consented to become the first President; the following gentlemen officiating as Vice-Presidents:—The Lord Rector (A. Bain, LL.D.), Sir Andrew Clark, Dr. J. Matthews Duncan, and John Farley Leith, Esq., Q.C. A provisional council, consisting of twelve gentlemen representing the different faculties, was appointed, and it was agreed that the first meeting of the club should be held in the month of May. The Honorary Secretaries of the new club are Dr. R. W. Burnet and Mr. R. M. Routledge, and any gentlemen desirous of becoming members are requested to communicate with them with as little delay as possible.

"TERMINAL Forms of Life", was the subject chosen by Dr. Cleland, of Glasgow, for the lecture which he delivered on Thursday week, under the auspices of the Glasgow Science Lectures Association. At the outset, Professor Cleland showed, from the investigation of organs, textures, development, and date of first appearance of animals, that these all combined to display animal life as a connected and progressive whole. They did not, however, and could not, prove a common ancestry, though certainly they suggested the raising of the question; and the more that observation bridged the gaps between groups far apart, the more possible such community of ancestry would appear. He explained that terminal forms in the animal kingdom, however they might have originated, had no power to advance to a higher level. Examples of these were given in detail from vertebrate and invertebrate forms: in the former, illustrations being taken from clamp shells, bivalves, starfish, and cuttlefish; while in the case of the latter it was shown that although there was an ascending series, consisting of fishes, amphibians, reptiles, birds, and mammals, the three last had proceeded from animals as low as amphibians, and that each division of reptiles and birds was terminal.

Dr. CLELAND next gave anatomical evidence, to show that the development of the vertebrate form had reached its limit in man; and that the animals most nearly approaching man were apes, of which the ourang and the gorilla were the highest. So far as the skull was concerned, the ourang was decidedly nearer to the human form than the gorilla. Man was a terminus, and not only a terminus but the terminus of vertebrate life. In defence of this proposition, he asked what had been the whole history of the advance of life from the simplest animals up to man but the growth of structure fitted for the exhibition of consciousness? After referring to the structure of the human body and brain, the lecturer said it seemed in the last degree improbable that, in the future, there would be a progression in the construction of the human body that would give birth to greater intelligence than the sages and heroes of antiquity.

OUR Glasgow correspondent writes, with reference to the Report of the Royal Infirmary, a summary of which will be found in our News column:—"It will be seen from the report that 156 fewer patients were admitted in 1883 than in the previous year. This, however, does not imply any diminution of the work done; as the average daily number has been greater, and the average residence longer. In reality, 5 per cent. more work has been done than in the previous year. There has been an unusual number of serious cases, more so than in any recent year, and, as might be expected in consequence, there has been a higher mortality. No fewer than 140 deaths, or about 28 per cent. of the whole, occurred within 48 hours of admission. The contemplated alteration in the number of physicians and surgeons, referred to in the report for 1882, has not yet been made; but at present the managers have under consideration a re-arrangement of the staff, whereby the dispensary physicians and surgeons may be called in to assist the visiting staff, thereby ensuring greater facilities and more time for clinical teaching, as well as greater medical attention for the patients and the training of the dispensary staff for future service in the wards."

SEVERAL deaths having occurred in the Royal Infirmary and other hospitals during the administration of anæsthetics, the managers directed their attention to ascertain whether any and what safeguards could be adopted. With that view they appointed a committee to inquire into the practice of other hospitals, and, after a protracted and careful investigation, certain regulations were unanimously adopted and are now in operation. Early last year the managers considered it necessary to revise the rules of the house, as a result of the above and other new regulations having been adopted, and amongst the changes made was a reduction in the period of continuous service of the physicians and surgeons from fifteen years to ten years.

Sir WILLIAM THOMSON, the distinguished Professor of Natural Philosophy in the University of Glasgow, has had a fresh honour conferred upon him; the Emperor of Germany having enrolled him among the Knights of the Order for Science and Art.

THE profession has lost another of the few remaining veterans who were in practice prior to 1815, the date of the passing of the first Medical Act. Peter Evershed, of Billingshurst, Sussex, died at Worthing on the 17th ultimo, in his 92nd year. He was born at Billingshurst, commenced practice there in 1813, was in active work there till 1863, and was buried there last week. He was one of the old school of practitioners, whose

first aim in life was the conscientious discharge of his duties in the place where his lot fell. Except for the few years of student life in London, he spent his whole life in the place of his birth, and he had so little reason to complain of his profession—in the fashion so prevalent now-a-days—that he brought up all his sons to it. His eldest son, who succeeded him in practice at Billingshurst, died, unfortunately, only two years after Mr. Evershed's retirement, but his remaining sons still survive.

An important public meeting was held at Liverpool on January 29, under the presidency of the mayor, to consider the means to be used in raising 40,000*l.* necessary for the endowment of two professional chairs and for the equipment of the chemical laboratory. When these additions are made to the teaching power of the university, it will be eligible for affiliation to the Victoria University, Manchester. It was announced at the meeting that the requisite amount, 10,000*l.*, was already obtained to endow one chair, and that nearly 7,000*l.* had been promised for the second. Mr. W. M. Banks said that, as far as the medical school was concerned, these additional endowments were necessary not only to the prosperity but to the very existence of that institution. For years they had successfully rivalled Owen's College, Manchester, but the foundation of the Victoria University, by giving that medical school the power of conferring degrees, had placed the Liverpool school at a serious disadvantage, which could only be removed by placing their school on the same footing as the Victoria University at Owen's College at present had. At the conclusion of the meeting, several further promises were announced, and no doubt the required sum will soon be forthcoming.

At the annual meeting of the subscribers to the Liverpool Royal Infirmary, itwas stated that the building fund now amounted to 107,000*l.*, but that no active steps had yet been taken, on account of the city council having withdrawn from the resolution granting them the wished-for site. It was confidently expressed that an amicable arrangement would soon be arrived at. During the year, 2,489 in-patients were treated at a cost of 12,860*l.* 14*s.* 2*d.*, or about 5*l.* per head. This expenditure was 812*l.* in excess of the income, and raises the existing debt of the Infirmary to 4,544*l.* 9*s.* 4*d.*

In proof of the attention being now paid in the United States to the position which the cultivation of the mental powers and physical exertion should hold towards each other, we may notice the fact that the University of Pennsylvania has instituted a Department of Physical Culture. "There is," says the *Medical Reporter*, "a great deal of attention paid to various forms of athletic and gymnastic sports throughout our land, but too little of it is guided by that which should be the moving principle of all, to wit, the improvement of health. Too often the consequences are detrimental rather than beneficial. Over-training, excessive exertion, ill-directed efforts, are as hurtful as judicious exercise is invigorating. There is ample scope for such a department. We need the lines to be drawn clearly, and the information to be scattered widely, as to the limit where muscular strain over-rides intellectual difficulty, and where it defeats itself by excess." The ignorance which prevails on the subject, even among professional men, the writer observes, is great, as indeed is shown in the very State in which this useful institution is about to be established, for Girard College, with 1,100 boys, has just removed a gymnasium which a few years ago it erected at a considerable expense. It is stated in the *Boston Med. Jour.*, however, that at the new Johns Hopkins University, at Baltimore, the prosecution of physical culture will be a part of the regular collegiate course, under the charge of Dr. Mussey Hartwell.

A painful fatality in the foot-ball field is reported from Bath. A young man, aged nineteen, in the course of an exceedingly rough game, received a blow on the head. He retired from the field, suddenly became unconscious, and died a few hours later. On post-mortem examination a large effusion of blood into the brain was discovered, the result of a ruptured artery.

Dr. Passant, in his report on the Paris Night Service for the last quarter of 1883, states that the total number of night-visits paid was 1,773, and of these 34 per cent. were paid to males, 51 to females and 15 to children under three years of age. The mean number of visits per night was 19·27 per cent. The total number of night-visits paid during 1876, the first year of the organization of the service, was 3,616, while during 1883, the eighth year, they amounted to 6,895.

The old story that Lord Brougham once wrote an entire number of the Edinburgh Review, rises unbidden to one's mind when one casts the first glance at the new publication, *The Asclepiad*, which Dr. B. W. Richardson has started, and proposes to carry on all by himself. It would be unjust to Dr. Richardson to apply to him all the sarcastic sayings which were predicated of his great forerunner. But *The Asclepiad*, an excellent title for such an undertaking, bears evidence of the same versatility and the same self-confidence on the part of the writer, as Lord Brougham was celebrated for. That *The Asclepiad* contains, and will always contain, so long as it lives—we hope it will live long—plenty of readable and suggestive matter goes without saying. Dr. Richardson has a large and full mind to liberate, and he never fails to liberate it pleasantly. But we hope his example will not be followed. A quarterly monograph from everyone in the profession who has "thoughts" and a facile pen would constitute an overwhelming portent. We hardly realize sufficiently how much those great safety-valves, the daily papers, save our be-lectured profession.

The St. John Ambulance Association, which has as its motto—*pro utilitate hominum*, has recently established a corps with a horse-ambulance carriage, and some two-wheeled litters, with properly-trained bearers, which is now ready to undertake the removal of sick and injured patients. The carriages are all built upon

the highly-approved pattern of Mr. John Furley, and the corps has the advantage of his personal supervision. It is within our experience that medical men are often at a loss to know how an invalid patient can best be transported in, to, or from the metropolis; now, all that they will have to do will be to communicate with the office at St. John's Gate, Clerkenwell, and the whole arrangements of the removal will be carried out for them in the most approved method. London has hitherto been behind the times in the matter of the transport of sick patients. The invalid carriages which were available for the purpose were ill-adapted for it, whilst their employment entailed such an expenditure of money, that they were beyond the reach of the many. We are glad to find upon the prospectus card of the corps that, moderate as their charges seem to be, in certain exceptional cases a reduction on the specified terms can be made, so that the advantages of the scheme may be experienced by the more necessitous members of the community. It is, we believe, hoped that the corps may be eventually self-supporting, as, indeed, it ought to be; but in the meanwhile the subcommittee appear anxious to undertake a considerable amount of unremunerative labour, in order that the profession and the public may become aware of the existence of the corps as well as of its fitness for carrying on its special work.

Her Majesty the Queen has consented to become the patron of the Home Hospitals Association for Paying Patients, and has given a contribution which will constitute her a governor of the association. Three years' experience of the working of the pay-hospital system, as tested by the association at their home hospitals, 16 and 17, Fitzroy Square, has shown that the demand for admission is much greater than the amount of accommodation at present provided. It was a portion of the original scheme, as submitted to the public at a meeting at the Mansion House in 1877, that if success attended the establishment of home hospitals for acute disease, home hospitals for convalescent patients should be opened at the seaside and elsewhere. The home hospitals for acute disease having proved in practice so complete a success, the committee have determined to establish a convalescent hotel, or home hospital, where anyone recovering from sickness will be received, and isolated, so as not to be a danger to others, whilst being freed from any influence which is likely to militate against his rapid and permanent recovery. It is proposed that each convalescent home hospital shall be provided with a resident medical officer, with skilled and competent nurses, and with a *cuisine* of a special character. Each inmate will find there neither the noise, the absence of privacy, the general bustle of an hotel, on the one hand; nor the damp sheets, slipshod attendance, and great discomforts of ordinary lodgings, on the other. At the present time, when a patient becomes convalescent—and when he is ordered by his doctor to seek change of air—where to send him becomes a question of difficulty and worry, in proportion to the serious nature of the attack from which he is recovering. A rapid recovery largely depends upon the wisdom of the choice; and the absence of the proper accommodation has not unfrequently produced a relapse. Indeed, the need of a convalescent home hospital for paying patients, for the treatment of patients recovering from infectious diseases, has become so urgently necessary that most families have—at some time or other—felt the want of such an establishment very sadly indeed.

It is proposed, further, to undertake to remove the patients from their residence to the home hospital, and to provide the necessary precautions *en route*, which are demanded by the public health as well as the patients' welfare.

It will be necessary to raise 10,000*l.* to enable the Home Hospitals Association to establish and open the convalescent branch. The association not being a commercial undertaking, but being registered at the Board of Trade as a philanthropic institution, has obtained the necessary capital previously on the same system as that which embodies the financial principle upon which the colleges at the universities and many of the public schools were originally founded. Contributors of fifty and twenty guineas each become eligible for election as governors and members of the association, with the privileges of obtaining—(1) Priority of admission for themselves and their families when ill, and of two nominations each year, if governors; and, (2) Of priority of admission for themselves only, if members. Owing to the demand for admission, a governorship at the present time confers substantial advantages, and the addition of a home hospital for convalescents will increase that demand, and enhance the value of governorships and memberships of the association.

The 10,000*l.* additional capital which the committee now requires to establish the home hospital for convalescents, will enable them to elect about three hundred new governors and members, and it is anticipated that the substantial advantages offered to heads of families, to bachelors, and other members of the community in return for their subscriptions, will be so much appreciated, that the applications for election—which should be addressed to the treasurer, care of Messrs. Cox & Co., Craig's Court, S.W.—are likely to far exceed the number at the disposal of the committee.

THE COMING SESSION.

Parliament meets early next week, and before our next issue is in the hands of our readers the profession will have been enabled, through the Speech from the Throne and the debate on the Address, to form a fairly clear idea as to whether any measures dealing directly with the public health are likely to be passed in the session that will have then commenced. It is stated that Government will re-introduce the Medical Acts Amendment Bill of last session, with some modifications, and that they intend to carry it. Of the worth and earnestness of that good intention we shall be better able to judge when we know positively what

great party measures Her Majesty's Ministers mean to introduce, and how many of those are to be pressed forward with all the power of the Government.

The Medical Acts Amendment Bill ought not to be re-introduced except with the stern determination that it shall pass. The need of some such measure has been recognised practically by ministry after ministry, but no Government has considered the matter of such importance as to really make their Bill dealing with it a measure that must be passed; and the list of Government Medical Bills that have been born only to die is becoming scandalously long. Yet it would not require, we believe, any great amount of steady persistence and watchful perseverance on the part of the present Government to pass their Medical Acts Amendment Bill. It cannot fairly be described as a revolutionary measure; nor is it in any way framed so as to unnecessarily arouse opposition. By the Medical Act of 1858, the whole of Her Majesty's dominions were thrown open to every medical man holding a licence to practise from a medical authority in any one of the three divisions of the kingdom; but this freedom was granted on a belief that all the licensing bodies required a fairly equal standard of knowledge to be shown before a minimum licence to practise could be anywhere obtained. Experience has shown that, however pretty and plausible that was in theory, it is far from perfect in practice; and one of the objects of the new Bill is to provide, so far as may be, for the uniformity in value of the lowest qualifications in England, Scotland, and Ireland. Another, and still more important, object is to secure that no person shall be admitted to the medical register with an incomplete qualification; that is, without having passed a final examination in medicine, surgery, and midwifery. Formerly, numbers of men were entered on the medical register with a qualification in medicine only, or in surgery only; and such is still possible, the clause in the Medical Act, 1858, which provided that medical authorities might combine for the purpose of granting a complete diploma, having remained all but a dead letter. The Government Medical Amendment Bill also provides for the so-called "direct" representation of the profession on the medical council, which is demanded by a large proportion of the profession; and in other ways also it reforms the organization of the council.

Taking it altogethar, the Bill ought, we think, considering how many years the profession has been troubled by an agitation for some measure of reform, to pass; and we certainly hold that the Government will not be justified in re-introducing it, unless with a settled and fixed determination to pass it. And if they are resolved that it shall pass, we cannot believe they would fail; the measure, if brought in at once in the House of Lords, would in all probability easily pass any ordeal that it is likely to meet there. It would then be sent without delay to the lower House, and there we may be sure that Mr. Mundella will promote it with all the required tact, diligence, and persistence, provided he is well backed by the Government. The question is, will he be so backed? Party spirit runs high, and the Medical Acts Amendment Bill is not a party measure. It is *only* a measure of public health, and public policy; and therefore it will run special risk of meeting with coldness and neglect till the end of the session is close at hand, when it may again be sent, with a pretty little funeral oration, by the Prime Minister to join that majority—the Slaughtered Innocents.

Not a few questions concerning the public health also loudly demand legislation; as, for instance, the subject of the notification of infectious diseases. But if the Government are determined to bring in Bills for the extension of the franchise and the re-distribution of seats, and the municipal organization of the Metropolis, such a common-place matter as domestic legislation will have to wait for wiser and better times.

POISON-VENDING

Several unfortunate cases have recently drawn attention to the facility with which poisons can be obtained, by even the least respectable persons, and many suggestions have been made with the view of preventing "accidents." But the question is not so simple as it seems. Restriction as to the sale of poisons is difficult. Noxious things are among the daily necessities of a civilised community. Phenol, oxalic acid, binoxalate of potash, and others must be retailed to the general public and to the workers in many trades without passing through the cycle of oral and written forms. If it were possible to enact and carry out a very strict Pharmacy Act, a hundred and one arts and industries, from etching on copper to washing linen, would languish. Imagine a Royal Academician desiring to purchase a tube of green paint, and having to give his name and address, to write it in a book, and to state the purposes for which he requires it! What stronger poison is there than tobacco? Half an ounce infused in water would make short work of even an inveterate smoker; but the absurdity of including tobacco in a Poisons Act is too obvious for discussion. Not a few would like to see laudanum and chloral controlled in a much more thorough manner than under the present law, but we are doubtful whether steps in this direction are really practicable. If a person will eat opium or is under the thraldom of chloral no law will prevent him, in any efficient manner, save at the expense of the general community, from purchasing what he requires. If no druggist is to sell more than a grain of opium to one person, the opium eater has but to go to twenty, thirty, or forty druggists until he has accumulated his dose. Some coroners seem to imagine that many suicides would be prevented if common poisons, such as phosphorus paste and the like, were prohibited from being sold at all; but we venture to think, that only that kind of suicide dependent on sudden impulse would be at all influenced by any greater restriction being imposed than at present. There are many doors of death; a man bent on self-destruction, stopped in one direction, succeeds in another. Remove the poison, he cuts his throat with a razor; remove knives and drugs, he suspends himself with his neckcloth.

To sell poison as poison, with a poison label on it, in a poison bottle, is one thing, but to sell it under a fancy name is another. The "soothing syrups," the "cough drops," the "remedies for spasms," the countless pills, elixirs, lotions, drops, and sleeping

potions which fill the druggists' shops, and their descriptions the advertising columns of the journals, are so many public dangers. A Lepcha once described the root of a glossy lurid-leaved Himalayan plant as "useful to sportsmen for destroying elephants and tigers, useful to the rich for putting troublesome relations out of the way, and useful to jealous husbands for the purpose of destroying faithless wives." In a similar spirit, looking at the long list of patent medicines of deadly composition, we may describe them as "useful to the insurer of the lives of others, useful to the expectant heir, useful to blight the shame-bud of illicit love, useful to the farmer of babies, and useful to all who have aught human to kill." The "powder of succession" can be bought for thirteen-pence-halfpenny; the "Aqua Toffana," has changed its name to "Somebody's infallible skin remedy;" the venom that smeared the Indian's arrow receives the English Government stamp, and pays the Government duty as a never-failing application for neuralgia or toothache. Let us have done with masks; sell each thing and let it be sold under its own name and no other, let soothing syrup be called "a solution of opium, dangerous to children;" let the exact strength and composition of odontalgic essences, of solutions of aconite, of chloral, &c., be stated on the label, and if wrongly stated let the offender be amenable to law. The time is ripe to say that licensed quackery should no longer be permitted in its present form; but that the ignorant and unscrupulous man who puts chloral solution in a bottle, colours it with cochineal, names it "Somnifer," or anything else that can be registered, and casts it broadcast by means of advertisement over the land, should be held responsible for its use and abuse. So long as the composition of medicines and poisons is known, so long as there is no secrecy, then there is fair protection both from accidental admixture and wilful ministration; but the present sale of poisons under the guise of patent medicines is not creditable to our laws, and is alien to our method of thought. We hope that an early effort will be made to take from the speculator and the charlatan the liberty they now possess of pressing the poisoned chalice to the lips of the credulous and simple.

IS MALINGERING OF NECESSITY A VICE?

In the daily papers of this week has appeared the account of a somewhat remarkable case of alleged imposture, which is described as having been enacted by a woman with the object of exciting the commiseration and charity of the benevolent. From the report of the inquest held on her body after death, it appears that this ingenuous female had, for a period of no less than twenty years, systematically feigned sickness, and was supposed by her family and friends during that time to have been suffering, first, from paralysis, and secondly, from a remarkable change in the colour of her skin, both of which were asserted to be the results of disease. This integumentary alteration, we are informed, consisted of the transformation of the individual in question from a blushing blonde into a sable beauty, the blooming fair complexion, with which she in common with other British virgins was formerly adorned, being in some mysterious way replaced by a shiny ebony black. This pitiable condition necessitated the most anxious care on the part of her relatives, her permanent confinement to bed, and constant seclusion in a darkened chamber, all of which distressing exigencies obtained for the sufferer universal sympathy, and doubtless even more substantial consolation. Shortly before her death, which took place as a result of acute phthisis, this interesting invalid volunteered the information that all her ailments during these years had been assumed, that her limbs in reality were as vigorous as those of others, and that the hitherto unaccountable skin affection was due to the unromantic external application of a burnt cork. It is satisfactory to learn that in this instance no member of the medical profession was the dupe of this gross and palpable imposture, so long and so successfully practised, as the lady had systematically declined to enlist the services of the faculty, owing, as she said, to her belief that science would be impotent to deal with her afflictions. The magistrate at the close of the enquiry, shrewdly remarked that it was unfortunate the accomplices of this duplicity could not be brought under the arm of the law as they richly deserved, it being clear that others beside the principal must have been implicated in the deception; and he further stated that, in his opinion, at least the mother and near relations could not have been altogether innocent of so clumsy a trick. Although we are not favoured with details in this particular, the profits of the nefarious transaction were doubtless satisfactory to those concerned, and the whole affair affords an illustrative example of the mingled cunning and credulity of mankind. Such an incident would be of more interest to the police than to the medical profession, did it not suggest that under certain circumstances the most flagrant cases of malingering may be the effects of disease, and the erring conduct the result of morbid mental states. In the present instance, the facts before us do not warrant any precise conclusions on this point, but it affords a text for some reflections on the subject.

There can be no doubt that some persons in indigent circumstances and of depraved moral character, in the pursuit of gain, will fully and systematically, by feigning disease, endeavour to obtain the pity and extort the charity of their neighbours. Such conduct voluntarily assumed for the purpose of direct imposition may unhesitatingly be stigmatized as vice, and should be exposed and punished as such. There exist, however, in a considerable section of the community, especially amongst women, certain constitutions which exhibit a peculiar mental condition, consisting of a moral obliquity, in which there is a morbid impulse, not wholly independent of volition, to deceive and mystify their fellow creatures, and that often without further reason than an apparent craving for sympathy, a longing for notoriety, and a desire to excite the interest and wonder of others. This condition is highly characteristic of the so-called hysterical state which is a well recognised nervous disorder, and from the earliest ages, and in every country, examples have been cited without number of the remarkable psychological distortions of those thus afflicted. Individuals so consti-

tuted, without apparent motive, have rendered their own existences miserable, have plunged their families into despair, and wreaked on society the most hideous of crimes; their intellectual faculties, properly so called, remaining to all appearances intact. The consequences of this condition must to a certain extent be regarded as the outcome of disease, although the border line between it and simple vice is extremely difficult to define, and the determination of it has always occupied and still occupies the serious and anxious attention of the physician and medical jurist. The uninitiated, finding the reasoning powers unaffected and the senses acute, are apt to resent a lenient view being taken of injurious or cruel acts performed under suspicious circumstances, and the opprobrious epithet of "mad doctor" is thrown at those who act for the defence. But the medical man who has studied the mental deficiences and moral perversions of such patients, from the smallest particulars to the greatest departure from sanity, knows that deeds, often apparently inexplicable, are to be accounted for otherwise than by crime. How far such departures from good conduct are to be punishable by law does, and always will, remain a delicate problem for solution, as while, on the one hand, society must be protected from injury, on the other, it must not be outraged by the persecution of the irresponsible.

The nature of this peculiar moral obliquity is not easy to analyse, but if we cannot explain its phenomena we daily see its effects. It is the attribute of all animals to cultivate the love and sympathy of their fellow creatures, an attribute which in distress or sickness is particularly augmented. If this natural desire is not satisfied, or if it is imagined that due consolation is withheld, it is a human failing with the best of us to make the most of our ills to obtain what we crave for. Within reasonable limits this display of our woes may be considered as an amiable weakness, indulged in to satisfy our natural affections. Beyond this, however, such exaggerations become morbid, and this condition is notably exemplified in the hysteric, whose abnormal cravings in this respect constitute disease. In this affection there is not only an excessive mobility of the entire system which initiates evils unknown to the healthy, but a special mental conformation which amplifies them in the mind of the patient, and excites an unreasonable demand on her part for the commiseration and consolation of others. From augmenting her existing ailments it is but a step to the manufacture of new ones, and the desire to simulate, to attract attention, and to display her misery becomes irresistible. From the smallest aberrations from truth, to the most profound dissimulation, these traits are common to all those suffering from this condition, and the instinctive duplicity, the incessant and inveterate inclination to be false in word and deed, without direct interest, is essentially a peculiarity of this remarkable malady. Besides the exaggeration of their complaints and the invention of others, hysterical persons have a special satisfaction in deceiving those around them, and more particularly their medical men, and their delight is as far as possible to render themselves scientifically interesting and mysterious, and, as it were, to place themselves on a pedestal for inspection. To effect this end the patient may evince unusual intellectual qualities, and the ingenious cunning, sagacity, and apparent good sense displayed by such subjects is notorious. It is not doctors alone who have been the dupes of such individuals, but from time immemorial the ignorant and superstitious public, ever ready to accept the supernatural or miraculous, have eagerly accepted their assertions and demonstrations as true.

When the hysteric has pursued this dangerous direction in excess, she is already on the threshhold of mental alienation, and from a medico-legal point of view, is not entirely responsible for her actions. Further, these profound and durable fixed ideas may so act on the mobile and unstable general system as to give rise to actual objective disturbances, which, although at first produced by volition, afterwards become genuine and beyond the control of the patient. Hence arise the excessive flow of tears, persistent vomiting, diarrhœa, and other functional derangements. It is finally not impossible that such persistent hallucinations may ultimately develop structural changes, as evidenced in chronic cases by the severity and incurable nature of the paralysis, rigidity, convulsions, and other phenomena sometimes observed.

Armed with knowledge concerning this form of nervous constitution, it is not surprising that the physician should recognise it in many examples of misconduct and crime, which appear inexplicable to the ordinary observer, but to him seem attributable to this cause. The case of imposture reported this week would appear to belong to this category, and is only remarkable from the length of time during which the imposition was kept up. Whatever may have been the motives which actuated those with whom the woman lived, it is difficult to believe that she was herself an example of a mere vulgar impostor. Assuming that a certain pecuniary advantage was to be gained, it is scarcely conceivable that any young person of healthy and well directed intellect would willingly incarcerate herself for twenty years, for that motive alone. Doubtless she attempted to deceive, but the puerility of the means she adopted, the length of time the trick was persisted in, and the paucity of advantage to be gained, all point to disease rather than to uncomplicated vice. It is not necessary for us to enquire at length into the motives of this particular female, or to attempt to further analyse the impulses of the class in general to which she probably belongs. The actions and nature of woman as a whole have puzzled wiser heads than ours, and philosophers from the most remote periods have vainly endeavoured to decipher her character. As medical men we can, however, from experience, assent in both a corporal and mental sense, to the dictum of the poet, "Frailty, thy name is woman."

Cholera at Madras.—An outbreak of cholera lately took place at Government House, Madras. Mr. Grant Duff and his family had just returned from Guindy, when his excellency's valet, an African, was seized with cholera, from which he subsequently died. By medical advice the family at once returned to Guindy, where they remain until the house is thoroughly disinfected. The medical men pronounce the case to have been of a purely sporadic character.

CLINICAL PAPERS.

No. V.—Optic Neuritis.

Since the invention of the ophthalmoscope, no one physical sign has proved so reliable as optic neuritis in the diagnosis of cerebral disease. Vomiting, headache, squint, an irregular pulse, may one or all be present, but it is optic neuritis which affords the clenching argument, the convincing proof of definite intracranial disease. Without it there is still room for doubt, with it there is no longer any excuse for hesitation in the diagnosis. So great a value then being set upon this sign, it is incumbent upon us to have, so far as may be, clear views as to the nature of optic neuritis and the causes which bring it about. As often happens when a new physical sign is made known, several explanations are offered of its mode of production, and the present instance is no exception to the rule; but until within the last few years no theory has been put forward that could by any reasonable amount of straining be made applicable to all cases.

The questions that naturally arise are: Firstly, What constitutes optic neuritis? Secondly, In what diseases does it occur? and lastly, How is it produced? We would define optic neuritis to consist in swelling of the disc, so that its margins are more or less completely obliterated, the surface being reddened or discoloured, the arteries narrowed, and the veins unduly full, tortuous, and perhaps lost to view at the margin of the disc. In advanced stages there may be hæmorrhages and other changes with which we need not concern ourselves. Amongst the causes we shall, for reasons which will subsequently appear, allot the first place to meningitis, then come tumour and abscess of the brain, softening from arterial obstruction, chronic Bright's disease, lead poisoning, certain acute diseases and acute anæmia, and perhaps some acute diseases of the spinal cord. It must not be forgotten that in some of these affections there may be only papillitis and not true optic neuritis, for it is as yet impossible, at any rate without unusual skill and experience, to differentiate by means of the ophthalmoscope between optic neuritis and papillitis. In all that we have to say, therefore, we put this latter on one side.

The first explanation put forward was that optic neuritis was of two totally distinct kinds: first, there was a true descending neuritis; and next, and more commonly, there was an inflammatory œdema of the optic nerve. The argument in support of the latter view ran very much as follows: Owing to the presence of a tumour or for some other reason, there was increase of the intracranial pressure; this led to pressure on the cavernous sinus, obstructing the return of blood from the eye through the ophthalmic vein, whence the production of œdema of the disc, followed by compression of the veins of the retina, giving rise to the condition known as "choked disc" of English writers. It was said that this form might ultimately lead to inflammatory changes. Just at first sight this theory was taking enough, but it was soon found out that the two forms were not to be so easily distinguished during life, and the one form was not unfrequently mistaken for the other. The theory received a great shock when it was shown how free was the communication between the ophthalmic, orbital and facial veins; and the discovery that the pressure of an aneurysm on the cavernous sinus does not necessarily produce a choked disc, gave it its death blow. Next there was the hypothesis that optic neuritis resulted from distension of the subvaginal or intersheath space behind the sclerotic by fluid which had spread from the subdural or according to some authorities from the subarachnoid space in cases of increased intracranial effusion; according to this hypothesis the neuritis would be due partly to pressure, partly to the transmission of an irritative action. This theory has enjoyed a more lasting favour than the preceding one, but cases of undoubted neuritis have occurred in which there was no distension of this sheath, and in some cases where the sheath was much distended no signs of neuritis have been recognised.

The next theory is that optic neuritis is set up by a tumour of the brain indirectly by vasomotor irritation; this may be quite true, but at present there is no evidence in support of it. It rests with those who hold this view to shew first that mere vasomotor disturbance is capable of setting up inflammation at a distance, and secondly that the optic nerve has, so to speak, vasomotor connections with all parts of the brain, for optic neuritis has been found to co-exist with tumours in the most varied situations. The theory of a descending neuritis has rapidly gained favour during the last few years, and, supported as it is by pathology, cannot fail ultimately to receive its due share of attention. Examination of the optic nerves reveals (what was denied by earlier observers) the existence of inflammatory changes in all cases of optic neuritis. These changes are found not so much in the nerve-tubes themselves as in the neuroglia and blood-vessels; and the latest explanation, and the one that seems the most satisfactory, is that in these cases the changes always originate in basic meningitis, and that where this is not present there optic neuritis will not be set up. This theory, based as it is on facts supplied by pathological histology, explains some facts which have hitherto been difficult of comprehension. For instance, in some cases of tumour optic neuritis is developed very late or not at all, and sometimes it will appear and pass off whilst the tumour is steadily increasing. In future we must not be satisfied in a case of optic neuritis that there is no meningitis without making a microscopical examination; nor in cases of basic meningitis must we consider the absence of optic neuritis as proved on the strength of a negative examination with the ophthalmoscope during life. With these words of warning we take leave of the subject, confident that, ere long, time will afford a complete and satisfactory solution.

Π

Hospital Saturday Fund.—At a meeting of the Hospital Saturday Fund, held last Wednesday in Exeter Hall, Mr. Arnold Morley, M.P., presiding, congratulatory addresses were delivered by the chairman, Mr. Hamilton-Hoare, Lord Brabazon, and others. It was also stated that the fund had reached a higher amount than in the previous year by the sum of 1,000*l*.

REVIEWS AND NOTICES OF BOOKS.

AGNEW'S SURGERY.—VOLUME III.[1]

With the completion of this volume, the third, of a system of surgery, terminates a task which has occupied the author's "leisure" for more than five years. The first volume appeared in 1878, the second in 1881, and the third has just been brought out, so that there has been no unnecessary delay in the production of the several parts of this voluminous work; and when it is borne in mind that the present volume is the smallest by some two or three hundred pages, it will be understood that, from first to last, there must have been incessant labour bestowed upon it. As regards the able surgeon whose name the work bears, the profession in this, as well as in his own country, will be glad to possess his recorded experience and opinions which are the outcome of much more than a quarter of a century of bedside observation and professional duties. But, in addition, the work gains largely from the contributions supplied to the author by numerous able collaborateurs to whom in the several prefaces Professor Agnew acknowledges his indebtedness. The valuable assistance rendered by these gentlemen, in collecting statistical and historical information, has been doubtless very great; indeed, without it, we cannot conceive how a work containing nearly 3,000 pages on so wide a subject as surgery could have been accomplished in the time. In turning merely over the leaves of any of these volumes, there are disclosed to the inspection vast and complex tables of hundreds of individual cases of one class and another, of injuries, operations, and diseases. Tables we find therein which represent days and weeks of searching, not in books only, but amongst the periodical literature of all countries; and these add largely to the value of the work as a storehouse of information, but they carry on their face the impression that no one brain could perform the task which has been accomplished under Professor Agnew's name in five, or twice five, years. And this impression deepens as the reader becomes more familiar with the text; and so does his foregone opinion that it is a step of doubtful wisdom and ambition, for one person to attempt to write upon the whole range of surgical subjects.

A manual for students must unquestionably embrace something of every department of the whole field. It must be complete and comprehensive, but at the same time concise. It need not contain anything that is original, and will certainly be all the better suited to its purpose if its aim is to present a good epitome of accepted doctrines and practice rather than to display the accumulated knowledge or special views of the author. Its pages may therefore, indeed should be culled from the writings of the latest and most experienced and best accepted workers in the various departments of surgery; and should not be made the repository of innumerable units of experience presented in detail, and then used for the deduction of general conclusions. For the busy practitioner, as for the student a compact, clear, and practical guide is needed; one which will at any moment of reference distinctly but briefly place the leading features of a disease or injury before him; one which will give him sound conclusions based on multiples of ripe judgments; one which will direct vividly the line of treatment, and the reasons for the treatment, without long narratives as to the why and the wherefore, the pros and the cons of every proposal. On the other hand, for the original investigator, for the lecturer, tutor or writer, a standard work of reference is required; for them the grounds on which the conclusions are based are welcome, the cases are independently studied by them, and the particular author's opinions are weighed and accepted or rejected, not received as unalterable and infallible guides to practice. To satisfy the latter a comprehensive encyclopædia is requisite; to meet the wants of the student and practitioner a good text book is needed.

Agnew's "Principles and Practice of Surgery" is neither the one nor the other, though perhaps it more approaches an imperfect encyclopædia than a text book. It is not, however, accurate enough, nor full enough, nor sufficiently equal in its treatment of different subjects for an encyclopædia; it is too profuse and diffuse to be recommended to students and practitioners. As a text book, it is not nearly so well adapted as Gross's "Surgery," the sixth edition of which appeared in 1882; whilst as a work of reference it will be lost sight of in the presence of the "International Encyclopædia of Surgery" which is now coming out, and of the "System of Surgery" edited by Holmes and Hulke, which has been before the profession for some time past.

We do not say this, however, disparagingly, nor in condemnation of the principles and practice as they are laid down in the work before us; on the contrary, it is only just to speak of the now completed work in the same terms of praise which we employed in reviewing the first two volumes; but it is, as we consider, the mistaken scope and handling of the subject-matter to which we refer.

Of this, the last volume, a great deal might be written. It contains chapters on the surgical diseases of the larynx and trachea; on the diseases and injuries of the nose, naso-pharyngeal region, and associated parts; of the eye and its appendages; and of the ear; malformations and deformities, and tenotomy in the treatment of "Orthopædia;" affections of the muscles, tendons, bursæ, and aponeuroses; surgical affections of the nerves; of the lymphatic system, skin, and subcutaneous connective tissue; syphilis; tumours; diseases of the mammary gland; electricity in its application to surgical therapeutics; operations for nerve-stretching; and massage. The value of the several chapters of course varies; the same amount of knowledge and care has not been brought to bear on all alike; and it cannot be said that they are all brought up to the point of information of the present time. On several subjects important recent views and researches are not even alluded to.

We had occasion to notice several omissions in each of the other volumes; and as in them so in this there

[1] The Principles and Practice of Surgery, being a Treatise on Surgical Diseases and Injuries. By D. Hayes Agnew, M.D., L.L.D., Professor of Surgery in the Medical Department of the University of Pennsylvania. Profusely illustrated, pp. 784, illustrations 511.

are numerous mistakes, evidently the result of hurry, such as errors in proper names and in references. There are, too, the same tabular groupings of so-called typical symptoms, for the sake of contrasting allied diseases, which are so frequently found in the other volumes, and which are so very suggestive of extracts from "cram" books on surgical diagnosis. But as in each of the other volumes so in this there are many valuable and important contributions to our knowledge, and several useful statistical collections. In the first volume the mass of material on fractures, and in the second volume the statistics of amputations, and the collected cases and records in the chapter on the surgery of the mouth, were very noteworthy; whilst in this third volume the information collected as to surgical affections of the nerves stands out as a prominent feature of much importance. The illustrations are, on the whole, superior to those in either of the other volumes.

The Sanitary State of the British Troops in Northern India; by SURGEON-GENERAL A. C. C. DE RENZY, C.B., London, Whitwy and Co.—This is a reprint of a paper read before the Epidemiological Society on February 7, 1883, which is of great interest with reference to the propagation of cholera and typhoid fever. Since the paper was originally produced, there has been added to it a preface, which, in some respects, is the most remarkable portion of the pamphlet. "It has been represented to me," says Dr. De Renzy, "that the paper does not accurately represent the views of Dr. Cuningham, inasmuch as, *though he holds that the specific germs of cholera and typhoid fever are not communicated through water, no one could, more strongly than he, feel and urge the importance of the purity of the water supply, as a preventive of such diseases.*" Dr. Cuningham's views, however, are well known, and the statements of them, made in the paper, are supported by extracts from his own writings; and it appears to us that the inaccuracy is not on the part of Dr. De Renzy, but of the author of this representation, who, failing to appreciate the divergence between the two authorities, makes an attempt to reconcile opinions, which are directly opposed to each other. Thus he loses sight of the fact that Dr. De Renzy considers the poison of cholera to be a specific poison, without which the disease cannot be produced, that the water carries this contagium, and is therefore the direct cause of the disease: whereas Dr. Cuningham holds that water does *not* carry the contagium, and therefore is *not* the direct cause of the disease, but that water contaminated with other impurities may injure the health, and so render people more susceptible of the cholera poison. The question therefore is not *how shall we reconcile these opposite views?* but *which of them is right?* In support of the opinion advocated in the pamphlet under review, we might quote numerous high authorities, pre-eminently Dr. Parkes, whom Dr. De Renzy himself quotes. But if Dr. Cuningham be right, all the direct observations of modern days, proving the affirmative, must be set aside, in favour of theories, held by a few only, but boldly put forward *as if* they proved a negative.

The evidence is most satisfactory of cholera having been, in a great number of instances, communicated from one person to another by liquids introduced into the mouth: knowing this, we must admit the possibility of its being sometimes communicated through the air, which is much more difficult to substantiate: but Dr. Cuningham denies that it is conveyed in either way, his idea being, as he stated at the meeting of the Epidemiological Society on July 4, that *no case of cholera has relation to any previous case.* Now this proposition is not susceptible of proof, and is negatived by numerous carefully investigated cases. To accept such a law is to set aside the plain evidence of reason, and must result in the cessation of all efforts directed against the true cause of cholera. Let us draw an illustration from some other disease, of which the contagium can be seen, such as favus. Dirt is well known to be a favourable condition for the development of favus, but the true cause is the *Achorion Schönleinii.* If any man were so rash as to deny this, he might allow a child to rub his head against another head affected with favus, simply taking care that cleanliness should be observed.

It is admitted by all that, in the evidence of cholera being conveyed by water, there is, up to the present time, one link wanting, viz., ocular or chemical demonstration, and Dr. Cuningham rejects all the other evidences, which have been considered sufficient by the best workers in this field of inquiry. For a private individual so to differ from his compeers is of small consequence, whether he be right or wrong; but if the Surgeon-General of India be wrong, it is a calamity of immense magnitude, for he leads millions astray on a subject involving the issues of life and death. However this may be, let him not close his eyes to the fact that, daily and hourly, the most accomplished investigators are bringing us nearer to ocular demonstration of the germs of this and many other diseases, as well as to verifications of their contagious nature founded on the experimentum crucis.

The history of Fort William very strongly supports the opinion that, when the water supply is so protected as to make contamination impossible, cholera is incapable of spreading to any serious extent, and this is also true of enteric fever. Thus, in the eleven years ending 1881, there were no fatal cases of enteric fever recorded in Fort William, and only ten deaths from cholera.

The review of Dr. De Renzy's pamphlet in a contemporary, contains an observation, to the effect that the author does not "explain why such remarkable fluctuations should take place in the death-rate, while the character of the water supply remains unchanged;" but the truth is it does not remain unchanged, for open watercourses in India are liable to temporary as well as permanent contaminations. A heavy shower of rain at Peshawur carries down a heap of filth, and alters the whole character of the water supply; at Lahore, on one occasion, a European employé of the railway complained that the body of a native, that had died of small pox, had been washed in the canal cutting, close to his dwelling; some days after the commencement of the terrible epidemic of cholera in 1872, a dead body was found in the watercourse, that supplied the drinking water at Meean Meer; and the immediate neighbourhood of these watercourses is continually dotted with the alvine evacuations of natives, whose favourite latrine is the bank of a stream, which furnishes, without the trouble of seeking, the means of immediate ablution. It is needless to point out the varying circumstances that may alter both the character and amount of the last-mentioned impurities. We earnestly recommend our readers to take all these points into consideration, before deciding that *fluctuations* in the death-rate throw doubt upon the causal relation of the water supply to the mortality.

ABSTRACTS AND EXTRACTS.

AN OLD CASE OF GASTROTOMY.

DR. HAGENS, of Dantzig, has lately communicated to the *Berlin. Klin. Wochenschrift* a case of gastrotomy performed in the 17th century, and described in a contemporaneous MS. now in Dr. Hagens's possession. The writer, however, Dr. Becker, published a much fuller account a few years later, under the title "De Cultrivoro Prussiaco Observatio et Curatio singularis . . . a Daniale Beckhero, Dantiscano . . . Regiomonti, 1636;" again, Lugd. Bat., 1638 and 1670. Two of his colleagues, also, G. Loth and R. Hemsing, issued reports of the case in German. Becker's book was translated into English by Daniel Lakin, as "A Miraculous Cure of the Prusian Swallow-knife, &c., 4to., Lond., 1642, pp. 147."[1]

[1] I have a copy of Lakin's book. Prefixed to it isa woodcut, showing the patient with the wound in the abdomen, and the knife. The book is, I think, very rare; my own copy being the only one I have seen. There is a curious collocation of names connected with this case. Daniel Schwaben did the operation, of which Daniel Becker wrote the report; Daniel Lakin translated it.—J. D.

The patient was Andreas Gruenheide, a peasant of Gruenwald, near Kœnigsberg. On May 29th, 1635, wishing to induce vomiting, he took up a table-knife by the blade and with the handle tickled his fauces. The knife slipped from his hold, and after a short delay in the œsophagus, entered the stomach. He tried the very simple plan of placing himself with his head downwards, but finding that the knife did not stir, he went to Kœnigsberg, and applied for advice to Dr. Becker. The whole collegium medicum of the city were invited to deliberate on the case, and a further opinion was requested from the medical faculty of Leyden. These learned doctors returned a solemn reply, divided into ten heads, finally sanctioning an operation. Dr. Becker encouraged the man to submit, by relating a similar case which had been successfully operated on at Prague, and then, on July 9, handed him over to Daniel Schwaben, "Surgeon and Lithotomist." All present having joined in solemn prayer for success, the man was bound to a plank, and the surgeon made a vertical incision below the false ribs on the left side, two fingers' breadth long.[2] The abdominal cavity having been opened, the stomach was caught up with a curved needle, and drawn forwards. In doing this the point of the knife was felt and cut down upon, then seized, and the knife drawn out. No attempt was made to close the wound in the stomach, which is described as spontaneously shrinking together. The external incision was united with five sutures, over which a most fantastically compounded poultice was applied. Nutritive enemata, it seems, were not thought of, and some soup was taken by the mouth on the very day of the operation, and was followed up by a powder and mixture. The patient appears to have resumed his ordinary diet within a few weeks after the operation. The wound healed completely; the man regained his health, and in 1643 was married; the name of the bride, and the date and place of marriage being duly recorded by Dr. Becker in his MS. Another proof that the patient was living several years after the operation, is afforded by a quaint entry in the *Diary* of John Evelyn. He visited Leyden, and under date of August, 1641, describes his visit to the anatomy-school, where, he says, "among other rarities I was shown the knife newly taken out of a drunken Dutchman's guts, by an incision in his side, after it had slipped from his fingers into his stomach. The pictures of the chirurgeon and his patient, both living, were there." In Becker's MS., in his book, and in Lakin's translation, the patient is shown with the incision in his abdomen; and in the margin the knife is depicted of its natural size. The blade and handle together measure about seven inches. Dr. Hagens, in concluding his paper, mentions the celebrated case of "l'homme à la fourchette" at Paris, and Félicet's "taille stomacale" for extracting a spoon; Schwaben's knife, he adds, completes the *Besteck*.

JAMES DIXON.

Harrow Lands, Dorking.

INVESTIGATIONS ON INTRA-OCULAR PRESSURE. — Dr. Ernst Gruser has published (*Arch. f. exp. Path. u. Pharm.* 1883, Bd. XVII., Hft. 5, p. 328), the results of some manometric investigations on the intra-ocular pressure, and the effect that atropine and eserine have upon it. By the aid of a specially-contrived apparatus, the author has arrived at the following conclusions:—1. By means of his manometer he is not only able to determine the amount of intra-ocular pressure or tension, but he can also detect and estimate with accuracy any variations of that pressure. 2. The amount of the intra-ocular pressure depends directly on the height of the vascular pressure. Narcotism similarly alters both, compression of the aorta raises the intra-ocular pressure by from 4 to 5 mm. Hg. Compression of the carotid on the same side causes a rapid fall of 5 or 6 mm. Hg., which, however, gradually rises again to the normal pressure. Tying both jugular veins raises the pressure, but only temporarily. The rapid fall of the arterial blood pressure which takes place at death is accompanied by a rapid fall in the intra-ocular pressure. 3. In a cat during life, the intra-ocular pressure is on the average equal to 28 mm. Hg.; when dead the pressure is always from 8 to 10 mm. Hg. 4. The movements of the muscles of the iris always affect the intra-ocular pressure, dilatation of the pupil always causing it to rise and contraction to fall. Section of the sympathetic causes a fall of from 2 to 6 mm. Hg. in the intra-ocular pressure as well as narrowing of the pupil; irritation of the same nerve causes a rise of the pressure of from 5 to 6 mm. with dilatation of the pupil. 5. Atropine applied to the conjunctiva in quantities sufficient to cause mydriasis raises the pressure (there is sometimes a transitory fall before the rise). 6. Eserine similarly applied causes the pressure at first to rise, but in all cases in less than an hour the pressure had fallen below the normal. (*Centralblatt f. Klinische Medicin*, Jan. 19, 1884.)

[2] This seems a very small opening; and, indeed, in all the three drawings, it is represented as a full hand's breadth from end to end. Lakin speaks of the "two fingers breadth" as indicating the point below the ribs where the incision was begun, not the length of the incision itself.

REPORTS OF SOCIETIES.

CLINICAL SOCIETY OF LONDON.

FRIDAY, JANUARY 25TH, 1884.

Sir ANDREW CLARK, Bart., President, in the Chair.

Mr. RIVINGTON read a paper on—

An Unusual Form of Dislocation of the Hip.

On August 5th, 1883, a man, æt. 34, was standing with his legs apart and his body bent forward, when some large packing cases fell upon him, striking him on the right side of the head and right hip. The head of the right femur was displaced from the acetabulum. The symptoms were complete immobility of the thigh, which was slightly flexed; abduction and commencing inversion of the whole limb, and shortening to the extent of three-eighths of an inch. Under ether it was readily reduced on the first employment of manipulation, the head entering the acetabulum with a click, and with slight grating. The dislocation differed from the ordinary sciatic form in the abduction, slight inversion, and less amount of shortening; and it did not resemble some published instances of anomalous displacements. It might best be described, perhaps, as the first stage of a sciatic displacement. On September 11, the patient, being able to walk, left the hospital cured.

Mr. RIVINGTON also communicated a case of—

Wound of External Carotid by a stab in the parotid region, Recurrent attacks of Hæmorrhage, temporary Ligature of the Carotid Trunk, combined with Ligature of the External Carotid at the seat of injury.

The patient, a carman, æt. 31, was stabbed by his wife in the left parotid region on December 24th, 1882. Hæmorrhage had ceased before his admission into the London Hospital, and his wounds were brought together by sutures. On December 30th and 31st some hæmorrhage occurred, but it was readily arrested by pressure. Swelling of the left side of the face and erysipelas supervened, necessitating incision and the insertion of drainage tubes. He went on well till Monday, the 15th of January, 1883, when severe hæmorrhage occurred, arrested by pressure with a sponge and bandage. On the following morning he was seen by Mr. Rivington. On removing the bandage and compress, blood gushed out in a strong jet from a wound over the position of the external carotid behind the jaw. Pressure stopped the hæmorrhage. To avoid loss of blood during the process of securing the wounded vessel, Mr. Rivington cut down upon the carotid above the ordinary seat of bifurcation of the common carotid, and passing a cat-gut ligature round one of the carotid trunks (either the common or external carotid), tied it so as to stop the current without

dividing the coats of the vessel. On removing the pressure from the wounded external carotid only a languid stream issued, and the vessel was tied above and below the opening. The ligature round the main trunk was then untied, but left under the vessel, and the wound was closed, the ends of the ligature passing out between its lips. No more hæmorrhage occurred, and the patient made a good recovery. The cat-gut ligature dissolved and came away from under the main trunk spontaneously on the sixth day after operation.

Dr. COUPLAND observed that a very similar case had been reported in a former volume of the Society's Transactions, and that the patient was present in the anteroom for examination.

Dr. DONALD HOOD related a case of—

Angina Pectoris, immediately followed by Pericarditis.

The history of the case was briefly as follows:—A gentleman, æt. 65, resting on a sofa, apparently asleep, was suddenly roused by the window curtains being on fire. He quickly jumped up to extinguish the flames, and within half an hour of this exertion he was suddenly seized with severe heart-cramp. Seen shortly afterwards by Dr. Hood, he was noticed as being blanched, barely able to speak, heart irregular and fluttering, pulse of peculiarly low tension, with agonising cramp-like pain over cardiac region. Hot stimulating applications, brandy, ether, and opium, were used freely, and the patient slowly lost the pain, and a general improvement of the circulation took place. Twenty-four hours after the commencement of the attack a soft pericardial shuffle was noticed; within a few hours it had deepened into a distinct rub. From this time during the succeeding ten days the case assumed all the characters of one of pericardial effusion; the amount of fluid being but moderate, and apparently completely absorbed within the ten days. A fortnight later the patient was found to have a systolic apex murmur, and symptoms of incompetency of the mitral valve rapidly developed. The patient died four months later from syncope, and at the time of death was the subject of cardiac dropsy. No *post-mortem* could be obtained. Dr. Hood suggested as a possible explanation of the primary attack, with its subsequent train of symptoms, that the patient was the subject of some fibroid degeneration of the heart. Roused from sleep by the flames, his alarm and exertions caused a sudden distension of the heart cavities, which possibly gave rise to some lesion of the visceral layer of pericardium, and so started the pericarditis. In support of this hypothesis, Dr. Hood called attention to the series of cases of fibroid disease of the heart, collected and published by the late Dr. Fagge in the twenty-fifth volume of the Transactions of the Pathological Society, and stated that in more than half of these cases the patients were found to have been the subjects of pericarditis. He further suggested that fibroid degeneration of the heart should be looked upon as a possible factor in those cases of pericardial effusion in which it was difficult to explain the cause of the pericarditis.

Dr. BURNEY YEO inquired if any evidence had been observed of possible arterial changes in this case.

Dr. DE HAVILLAND HALL gave the details of a case seen by him five years ago, in which a man, aged 56, had suffered from severe pain in the præcordial region shortly after a violent and passionate altercation with his son. The pain was still present on the following day, but was somewhat relieved by the use of diffusible stimulants, and of morphia subcutaneously, but never quite disappeared. The sounds of the heart were then normal, and there was no rise of temperature. Within forty-eight hours, signs of pericarditis became manifest, a moderate effusion took place, the patient became worse, and died in four or five days. No *post-mortem* examination was made.

In reply to Dr. GLOVER, Dr. Hall stated that there had been a slight rise of temperature on the third day.

The PRESIDENT observed that, as the cases of true angina pectoris were almost always relieved by the use of even the most minute quantities of nitro-glycerine, he should like to ask why Dr. Hood had not made use of it in his case. He inquired further, what had been the course of the temperature, and commented upon the fact that some cases of pericarditis may run the whole of their course without giving rise to pyrexia.

Dr. DUCKWORTH thought it only fair to say, that hitherto no clinical connection had been recognised between cases of genuine angina pectoris and pericarditis by any of the standard authors. The classical disease, angina pectoris, was generally relieved by the well-known remedies. But there were other forms of angina, and especially in connection with aortic disease, in which severe cardiac pain was set up, and he considered it possible that the cases related might have been of this class. Chronic mediastinal inflammation, disturbing the nerves of the part, might give rise to cardiac neuralgia. These cases, however, were different from those of true angina pectoris. He thought that probably very few physicians had seen many cases of the latter affection, whilst the occurrence of cardialgia must be familiar to most observers. Simple cardiac neuralgia, however, was not usually followed by pericarditis.

Dr. W. EWART thought that it would be of interest if evidence could be brought forward of the extent to which pathological changes on the heart and great vessels could give rise to symptoms. He had met with many instances of cardiac pain simulating neuralgia, brought on simply by excitement. It would be difficult to explain the occurrence of pericarditis from a purely functional cause; but he thought it possible that there might be an enlargement of the aorta within the pericardium, which escaping detection, might suffer a slight rupture and so set up pericarditis. He would be inclined to attribute the sequence of events in these cases to some such coincidence.

Mr. COODE ADAMS mentioned a case, in which a slight rupture in the wall of a fatty heart had led to hæmorrhage and subsequent fatal pericarditis. In this case also there had been pain resembling that of angina pectoris.

Dr. HOOD, in reply, explained that in his case nitro-glycerine had not been at hand, and good results had at first been obtained by diffusible stimulants. The temperature throughout the case had remained normal. The renal functions were natural, and no arterial changes had been detected. The possibility of aneurism had been fully discussed at the time; but even if such a condition had been present, it would have afforded no explanation of the subsequent endocarditis.

Dr. DE HAVILLAND HALL read the following case of

Empyema, followed by Abscess of the Brain.

S. N., æt. 19, a pupil teacher, admitted into the Westminster Hospital, August 20th, 1883. The patient had empyema, following an attack of acute pleurisy, three years previously. She had been tapped, and a drainage-tube left in. When first seen by Dr. Hall at Christmas, 1881, she was suffering from hectic in consequence of imperfect flow of pus; immediately, however, that perfect drainage was established, her condition improved, and for a year she was able to resume her duties. The reason of her last admission into hospital was the hope that the chest had sufficiently fallen in to allow of the withdrawal of the drainage-tube; but when this was done the evening rise of temperature which occurred showed that pus was accumulating, and the tube had again to be introduced. Just as the patient was about to return home, she began to complain of headache; this was followed by vomiting. On the 11th day from the onset of cerebral symptoms the temperature, which previously had been subnormal, began to rise. There were slight convulsions on the left side of trunk and face, the drowsiness became more profound, and she died comatose. Shortly before death there was a copious purulent discharge

from the left nostril. At the *post-mortem* examination, which was made by Dr. Hebb, the left pleura was found extremely dense, a cavity capable of containing several ounces of fluid lay between the opposing surfaces; elsewhere the parietal and visceral pleuræ were united. On removing the brain, an abscess in the left posterior lobe burst; no other pathological appearance was detected. The abscess, spherical in shape, and about the size of a hen's egg, lay in the white matter, the walls were nearly an eighth of an inch thick, hard, and of a purplish brown colour; the contents were a thick greenish pus, which had an offensive odour. In commenting on this case, Dr. Hall insisted on the importance of having a double opening in cases of empyema, the lower one being made, if possible, in the eleventh interspace—a drainage-tube being passed through the two openings, and the ends tied together. By this means perfect drainage is attained. He claimed the case under consideration as a success, so far as the empyema was concerned, as the treatment was so far beneficial that the patient was able to resume her duties; whereas, prior to the double opening being made, she was much exhausted by the constant suppuration, and consequent hectic. Turning to the question of cerebral abscess, Dr. Hall mentioned some cases in which this disease had followed empyema. In his case the thick abscess wall pointed to its being of many months' duration; the absence of symptoms till towards the end being explained by the seat of the lesion being at a distance from the motor and sensory centres, which apparently were not compressed. The two symptoms which ushered in the terminal period, viz., headache and vomiting were those commonly observed in such cases. He was unable to give any explanation of the discharge of pus noticed from the left nostril shortly before death. At the autopsy, in spite of careful search, no appearance of suppuration was detected at the base of the brain, and there was no communication between the abscess and the nose.

Dr. Burney Yeo expressed his conviction that the best operative means of evacuating pus from the pleura, was that of excision of portions of ribs, as carried out by Sir Joseph Lister at King's College Hospital. He made especial mention of three cases, in all of which the most satisfactory results had been obtained. The opening had generally been made in the seventh intercostal space in the posterior axillary line. This spot was not chosen arbitrarily, but was generally indicated in each case. It was preferable to any point lower down, because of the frequent accumulation of thick layers of fibrin at the more dependent parts, and also because of the fact that the ribs in such cases are usually closely approximated to one another below the level of the eighth rib. He remarked upon the preference of German surgeons for selecting the anterior parts of the chest, from the same reasons.

Mr. R. W. Parker contended that the best position for operating, and the best method of performing the operation could not be positively laid down. Many empyemata were loculated, and we must operate upon them where we find them. He could not share Dr. Hall's satisfaction with the result of his case, believing that a more thorough evacuation would have led to a cure, rather than to the temporary relief, followed by complications and death. The chief difficulties in such cases were met with towards the end, owing to the rise of the diaphragm or other causes, whereby drainage tubes were liable to become obstructed. He considered that the advantage of double openings in the chest wall were unmistakeable, but would prefer to obtain the same results by passing a double tube through a single opening. Such an opening, however, must be wide and free, so as to enable large tubes to be used, and with this precaution he did not find any advantage in excision of portions of ribs. In some of his later cases he had been able to remove a considerable amount of thick pyogenic membrane by the aid of a sharp spoon fixed in a flexible handle.

Mr. Pearce Gould, who had seen and operated on Dr. Hall's case, admitted that the ultimate result had been unsatisfactory; but called attention to the marked relief afforded by the operation, pointing out that, under the circumstances, further operative interference seemed uncalled for. With respect to the abscess in the brain, it was difficult to trace any connection with the empyema. The temperature chart showed most clearly that there had been no fever for a long time before death. The septicæmic nature of the abscess was therefore doubtful, but even such cases as these had been known to run an apyrexial course. He suggested the possibility of the abscess being formed from a softened tuberculous mass. In operating on the present case he had chosen the seventh space for the opening, because the diaphragm had not risen and drainage was free. Perhaps in the later stage of the case it would have been better to have used only the upper opening. When the chest wall falls in, all the ribs come closer together with the exception of the eleventh and twelfth, between which there remains a space, probably due to the traction of the quadratus lumborum muscle. He agreed with Mr. Parker as to the value of the double tube, but related a case in which perfect success had been obtained with a single one.

Mr. R. J. Godlee drew attention to the purulent discharge from one nostril which had occurred in Dr. Hall's case, and asked whether there had been any evidence of disease of the nose itself, or of the ears, which might have given rise to the cerebral abscess. In operating for empyema he preferred to make a single free opening, not too low down, with excision of portions of one or more ribs. There were many advantages in the system of large single openings, and it was not open to any serious objections or evil results.

Mr. Barker agreed with the advantages attributed to the single opening with excision of portions of one or more ribs. He had been struck, not only with the ease, but also with the rapidity, with which the operation could be carried out. The sub-periosteal removal of rib was, however, frequently followed by regeneration of bone before falling-in had begun to take place.

Dr. Percy Kidd had had opportunities of making *post-mortem* examinations in two cases of cerebral abscess following empyema. Both cases had been operated on by Mr. J. Marshall. In one case a portion of rib had been removed, and in the other a small portion of rib was found to be bare. In this case death occurred in five days.

The President pointed out that these cases of pericarditis and of empyema had served to illustrate a point worthy of remembrance, viz.: that, under certain conditions, inflammation may take place without any rise of temperature. He believed that septicæmia, or even fever, might occasionally present all their phenomena with the exception of pyrexia. Between the contending advocates of the double opening, and of the excision of ribs, he feared that the old-fashioned plan of drainage through a single opening ran some risk of being lost sight of. He related the particulars of a case of long standing in which, with strong family predisposition to phthisis, the patient made a good recovery after simple drainage. The occasional collection of small quantities of pus in the pleura had given rise to small storms of fever from time to time.

Dr. Hall, in reply, observed that the question of excision of ribs had been suggested, and he recapitulated some of the features of the case which had determined the treatment adopted. With respect to the abscess in the brain, there had been no evidence of nasal or aural mischief, nor was there anything in the *post-mortem* appearances to suggest tubercle. From the appearance of the abscess cavity it had clearly been a long time in forming.

Death of a Medical Practitioner from Morphia.—An inquest was held on Friday, the 25th ult., on the body of Dr. W. O. Deacon, medical officer of Richhill, Ireland, who died after injecting five grains of morphia. From the evidence, it appeared that the deceased had been in the habit of administering to himself ten grains of the drug twice a day for the last four or five years.

MEDICAL NEWS.

THE ROYAL COLLEGE OF PHYSICIANS.

At a meeting of the Royal College of Physicians of London, held on Thursday last, after some formal business, the following communications were received: From the President, stating that the Swiney Prize, a quinquennial prize, had been awarded to Professor Sheldon Amos; from Sir Joseph Fayrer, a report on the Amsterdam Intercolonial Congress; from the Northumberland and Durham Medical Society, thanking the College for their re-entombment of Harvey's remains; from the Secretary of the Harveian Society of London, sending a similar resolution; from Sir William MacCormac, late Secretary-General of the International Medical Congress, presenting photographs and autographs of the members of the Congress; and from the Rev. John Escreet, in reference to the restoration of Hempstead Church, stating the estimated cost; and again asking for assistance. The College, as a college, decreed they had no funds for the purpose.

Drs. Herbert Davies, Hermann Weber, Lockart Robertson, and Moxon, were elected councillors in place of Drs. G. Johnson, Fincham, J. E. Pollock, and Andrew, who went out of office.

A report was received from the Censors Board, on the paper by Drs. Sydney Ringer and Murrell on Nitrite of Sodium. The Censors consider that mistaken inferences were drawn from the paper, owing to its unfortunate construction. They regretted this, but entirely acquitted the authors of improper experimentation, and consider they have really rendered good service to the profession.

Dr. Ord and Dr. Dickinson were appointed Examiners for the Murchison Scholarship.

Drs. Stevenson, Corfield, Ballard, and Thorne, were appointed Examiners for the Certificate in Hygiene.

The Council recommended that the President of the College, and the President of the Royal College of Surgeons, seek an interview with the Home Secretary as to the necessity of providing for the proper instruction of the Public Prosecutor in the case of criminal charges against medical men; and the College accepted that view.

A report was received from the Pharmacopœia Committee, suggesting changes in the new edition of the Pharmacopœia.

British Medical Benevolent Fund.—The annual general meeting of subscribers to the British Medical Benevolent Fund was held on Jan. 15th, at 34, Seymour-street, Portman-square, the house of the treasurer, Dr. Broadbent, Dr. G. C. Jonson taking the chair in the unavoidable absence of the President, Sir George Burrows.—The financial statement was submitted, and the annual report of the committee read by the treasurer, from which it appeared that the donations during the year 1883 had amounted to 542*l.* 6*s.* 5*d.*, the subscriptions to 1,376*l.* 6*s.* 4*d.*, making a total of 1,918*l.* 12*s.* 9*d.*—The disbursements during the year had been: in grants, 2,229*l.*, nearly 100*l.* more than in any previous year; in annuities, 1,062*l.*, a total of 3,291*l.*; and the entire expense of collecting and distributing this large sum amounted only to 141*l.*, not 4½ per cent., including the printing and postage of the report and also the postage and other expenses connected with the distribution of over 2,000*l.*, by Dr. Jonson, chairman of committee, in weekly or monthly instalments—a peculiar characteristic of this fund. At the last meeting of the year, the balance at the bankers was entirely exhausted, and every farthing at the command of the committee voted away. During the year, grants were made to 190 applicants, after careful enquiry, ranging from three pounds to enable an assistant to take a situation to one of twenty-four pounds in monthly instalments of four pounds, by means of which the use of his furniture was secured to an aged practitioner. The committee again wish to point out that, although large sums are sent up by the various honorary local secretaries, it is a fact that those parts of the country from which the most urgent appeals come do not contribute to an equal extent with others from which the appeals are neither so frequent nor so urgent: showing a want of more honorary local secretaries to the Fund. Dr. Milson and Mr. Kiallmark joined the committee; and Dr. G. C. Jonson and Sir Edwin Saunders were elected vice-presidents of the Fund.

University of Edinburgh.—The annual meeting of the Association for the Better Endowment of the University of Edinburgh was held on the 25th ult. The report stated that the income from matriculation and graduation fees was 8,949*l.*, and from other sources 4,198*l.*; the expenditure amounted to 10,207*l.*, leaving a surplus of income of 2,940*l.* To render the financial position of the university less precarious, it was greatly to be desired that some very substantial addition should be made to the capital of the general university fund. The insufficiency of the emoluments of the principalship and many of the professorships had frequently been pointed out in detail. The committee now only stated that these remained in the same unsatisfactory condition. The new buildings for the medical school of the university were so far advanced that all the lecture rooms, and most of the practical teaching rooms, were in use. The sum as yet contributed towards the new subscription for the completion of the buildings was barely sufficient to meet the cost of the teaching departments, and even when these should have been completed, the University of Edinburgh would remain without a hall for graduation ceremonies, examinations, and university meetings, such as the munificence of the Marquis of Bute had bestowed upon Glasgow University. That was an ever-felt want in the University of Edinburgh, which would be especially apparent at the approaching tercentenary celebration.

Glasgow Royal Infirmary.—The annual report shows that during the year the total number of cases treated was 32,952 against 32,687 in the previous year. The income from all sources during 1883 was 29,570*l.* 5*s.* 6*d.*, and the total expenditure, 27,646*l.* 18*s.*, showing a favourable balance of 1,923*l.* 7*s.* 6*d.* There were admitted during 1883, 5,445 cases, against 5,601 in 1882, being a decrease of 156; the cases treated to a conclusion numbered 5,465 cases, against 5,564 in 1882, a decrease of 99; and the deaths were 499, against 446 in 1882, an increase of 53. The mortality was thus 9·1 per cent., against 8 per cent in 1882, but of the fatal cases as many as 140 died within 48 hours of admission against 103 who died under the same circumstances in 1882. The mortality (excluding those who died within 48 hours), was 6·7 per cent. The daily average of patients resident was 509, against 507 in 1882, and the average residence of each was 33·4 days, against 32·2 days in 1882. The non-resident accident cases treated in the wards numbered 1,326, against 1,312 in 1882; the number under 15 years of age treated was 878, against 985, and the deaths 48, or 5·4 per cent., as compared with 53, or 5·3 per cent. in the previous year. The lowest number of patients in the house was 439, against 444 in 1882; the highest number in the house was 555, against 549. The patients treated at the dispensary were:—Medical, 9,609, surgical, 11,727; in all 21,336, against 21,197 in 1882. In the special dispensary departments, that for the throat had 468 patients, against 586; the ear, 1,444, against 1,136; women, 337, against 289; skin, from 7th Nov., 68 (new branch); teeth, 976, against 1,011. Vaccinated, 1,532, against 1,592. Total treated, 32,952, against 32,687. Patients sent to Lenzie Convalescent Home, 584, against 634.

Glasgow Eye Infirmary.—The annual report of the Glasgow Eye Infirmary, submitted at a meeting of the subscribers on Friday the 25th ult., showed that the total number of cases under the care of the medical officers during the past year was 13,697, as against 13,207 in 1882. Of these cases, there were dismissed, cured by ordinary treatment, 6,998; cured by operation, 1,424; relieved by ordinary treatment, 1,167; relieved by operation, 168; incurable, 50; with advice, 21; as irregular, 10; and there remained on the books of the institution on 31st December last, 3,859. Of the cases, 7,701 were dealt with in Berkeley-street, and 5,996 in Charlotte-street. The number of house patients in 1883 was 1,015: of these, 625

were males, and 390 were females. The average weekly number was 54, and average length of each patient's residence was 19¼ days.

The Hospital for Sick Children.—A special court of the governors of this institution was held on the 23rd ult., when the general report was presented by the secretary, Mr. Samuel Whitford. It appeared that the hospital had been enabled to keep the whole of the various departments in full and satisfactory operation, although the state of the finances was not so satisfactory as could be desired. Mr. A. Lucas said that, unfortunately, the drainage of the building was somewhat defective, the old system in vogue at the time when the present structure was erected having failed to carry out efficiently its object over such a lengthened period; the sewers were old and the connections bad and unsuited for the purpose. Dr. Buchanan had recommended the committee to call in the services of Mr. Field, of the Sanitary Department of the Privy Council, and that gentleman had sent in a report, which was then submitted for the consideration of the special meeting. To carry out the suggestions made in that report it would be necessary to expend a considerable sum of money. After some conversation the following resolution was unanimously carried:—"That this court approve of the expenditure of the sum of money required for the construction of the proposed works in connexion with the drainage of the hospital."

Metropolitan Convalescent Institution.—At the half-yearly general meeting, held on Tuesday, it was stated that upwards of 4,000 convalescent men, women, and children were received each year into the homes. The remaining portion of the Bexhill Home will be opened as soon as the necessary arrangements are made, and when completed it will accommodate 100 persons. Owing to the want of funds, the board of management have been obliged to reduce the stay of the patients at the homes to three weeks, and unless the income is considerably increased they will have to reduce the number of beds. The total income for the year amounted to 7,958*l.* 17*s.* 6*d.*, and the expenditure to 7,723*l.* 0*s.* 5*d.*

The Crusade Against Vaccination.—It is reported that, notwithstanding the overwhelming defeat last session of his anti-vaccination motion, which was rejected by 286 votes to 16, Mr. P. A. Taylor has determined once more to challenge the judgment of the House of Commons on the same topic. This year, however, instead of proceeding by way of motion, he will bring in a bill for the repeal of the compulsory clauses of the Vaccination Acts. Several members—among them Sir Joseph Pease and Mr. J. R. Hollond—who are not disposed to support absolute repeal, are prepared, nevertheless, to restrict the infliction of cumulative penalties, and it is understood that the Local Government Board itself is adverse to the repeated prosecution of parents who conscientiously object to vaccination.

Irish Graduates' Association.—Dr. Gerald Yeo will preside at the annual dinner of this association, to be held on St. Patrick's Day, at the Holborn Restaurant, at 7.30 p.m.

French Hospital.—The annual dinner in aid of the funds of the French Hospital and Dispensary will take place at Willis's Rooms, on Saturday, February 2, 1884, the French Ambassador in the chair.

Army Medical Department.—There will be three retirements under the age clause during the present year from among the administrative ranks of the Army Medical Department, viz., Surgeons-General A. Smith, C.B., and J. Lamprey, on October 14; and R. Gilborne, on November 20.

Edinburgh University.—The Vienna University has decided to forward a congratulatory address to the Edinburgh University on the occasion of the latter's tercentenary celebration.

Female Medical Students.—It is stated that all the female medical students in St. Petersburgh, a class from which a daily contemporary states many redoubtable members of the nihilist party have emanated, have just been compelled to take up their residence in a large boarding establishment, provided by the authorities, under the superintendence of Princess Shakafskey, instead of being free as heretofore to live where they please. They are to pay ten roubles per month for board and lodging, and be at home before 9 o'clock in the evening, under penalty of exclusion from the medical course.

South Devon Hospital.—The Earl of Morley presided, on Tuesday, at the annual meeting of the South Devon Hospital, Plymouth, for which a new building is to be opened shortly, at a cost of 30,000*l.*

Charitable Bequests.—Mr. Dodgson, of Beardwood, near Blackburn, has bequeathed 10,000*l.* to the Blackburn Infirmary, 10,000*l.* to the Royal Albert Asylum for Idiots and Imbeciles at Lancaster, and 5,000*l.* to the Manchester Infirmary.

Royal College of Surgeons of England.—The following gentlemen, having undergone the necessary examinations for the diploma, were admitted Members of the College, at a meeting of the Court of Examiners on the 24th ult., viz.—

Adams, C. E., Carno, Montgomeryshire.
Carter, A. J., Harleyford Road, S.E.
Crowle, T. H. R., Campdenhill Road.
Davis, W. P., Ebury Street, S.W.
Fuller, G. H. H., New Shoreham.
Gooding, M. R., L.R.C.P. Lond., Oakley Square.
Harvey, James, Leicester.
Hughes, E. A., Bentinck Street.
Johnson, G. H., Wath-on-Dearne, Yorkshire.
McDonnell, W. C., L.R.C.P. Lond., Stoke Newington.
Power, E. T., Denmark Hill, S.E.
Robbs, C. E., B.A. Cantab, Powys Square.
Spicer, W. T. A., B.A. Cantab., Saffron Walden.
Styam, T. G., M.A. Cantab., Eastbourne Terrace, W.

Three candidates passed the examination in Surgery, and when qualified in Medicine will be admitted Members of the College; four candidates, having failed to acquit themselves to the satisfaction of the Court of Examiners, were referred to their professional studies for three months, four for six months, and one for nine months.

The following gentlemen passed on the 25th ultimo viz.:—

Barrett, J. W., M.B. Melb., Melbourne.
Carroll, E. R. W. C., Wokingham.
Dill, J. F. G., M.B. Cantab., Lower Belgrave Street.
Edlin, H. E., Manchester.
Edwards, D. G., Denbigh.
Eleyatamby, Mudalitamby, L.R.C.P. Ed., Colombo.
Hawkins, G. C., Teignmouth.
Rogers, W. F. C., Falmouth.
Ross, E. F., L.R.C.P. Lond., Sydney, N.S.W.
Taylor, Robert, Mendlesham, Suffolk.
Thomas, A. W., L.S.A., Clapham Common.
Wale, George, Carshalton.
Webb, Hugh, Buckingham Palace Road.

Five candidates passed in Surgery, and when qualified in Medicine will be admitted Members of the College. Seven candidates, having failed to acquit themselves to the satisfaction of the Court, were referred for six months, and three for three months.

The following gentlemen passed on the 28th ultimo, viz.:—

Bird, Henry, L.S.A., Brampton.
Carnelley, Matthew, Fallowfield.
Evans, Cadwallader, E., Bristol.
Gostling, John H., Halesworth.
Growse, William, Brentwood.
Habgood, William, L.S.A., Wimborne.
Hudson, Charles L., L.S.A., Bungay.
Lewis, Edward J., B.A. Cantab., L.S.A., Llandovery.
Lilley, James H., M.A. and M.B. Cantab., Atherstone.
Marriner, William H. L., L.S.A., Gunterstone Road, W.
Pilgrim, Herbert W., L.S.A., St. Augustine's Road, N.W.
Samut, Richard, L.S.A., Malta.
Townsend, Edward B., L.R.C.P. Ed., Colchester Street, N.W.
Vince, John F., L.S.A., Birmingham.
Warner, Frederick A., Kensington.
Wholey, Thomas, L.R.C.P. Lond., Gainsboro'.
Woolby, James B., L.R.C.P. Lond., Halesworth.

Four candidates were approved in Surgery, and when qualified in Medicine will be admitted Members of the College. One candidate was referred for nine months, five for six months, and three for three months.

The following gentlemen passed on the 29th ultimo, viz. :—

Bean, Charles E., L.S.A., Shepherd's Bush.
Benson, Christopher R., L.S.A., Clifton.
Crocker, John H., L.S.A., Gunnislake, Devon.
Cummings, Harold L., L.R.C.P. Lond., Dulwich.
Edgelow, Herbert, Cambridge Street, Pimlico.
Foley, Charles N., L.S.A., Denbigh Place, S.W.
Holroyde, John, L.S.A., Ripponden, Yorks.
Irvin, Frederic D., L.S.A., Longridge, near Preston.
Julyan, Francis H., L.R.C.P. Lond., Queen's Park, W.
Nuttall, Charles D., L.R.C.P. Lond., Leicester.
Parry, Herbert L., L.R.C.P. Lond., Canonbury Park North, N.
Smith, John C., L.S.A., St. John's Wood.
Whish, Martin S., L.S.A., Granby Street, N.W.

Three were approved in Surgery, and when qualified in Medicine will be admitted Members of the College; seven were referred for six months, and two for three months.

The following gentlemen passed on the 30th ultimo, viz. :—

Armitage, Edward H., L.R.C.P. Lond., Brook Street, W.
Clarke, Charles F., L.S.A., Plumstead.
Dodd, Arthur H., L.S.A., Petherton Road, N.
Gordon, Thomas E., M.B. Durham, Gower, Swansea.
Mills, Robert, L.S.A., Northampton.
Minns, Allan G., L.R.C.P. Lond., Thetford.
Opie, Edward A., M.B. Durham, Plymouth.
Rowlands, William, L.K.Q.C.P.I., Great Crosby, Liverpool.
Scutt, Tom., L.R.C.P. Lond., Wareham.
Stables, Alexander, M.B. Edin., Nairn, N.B.
Stott, Hugh, L.S.A., Uxbridge Road.
Webster, Alfred G., Huddersfield.

Eight candidates, having failed to acquit themselves to the satisfaction of the Court of Examiners, were referred to their professional studies for six months. 191 candidates presented themselves for the examination just completed, as compared with 175 at the corresponding period of last year: of this number 20 were referred to their further professional studies for three months, 59 for six months, and two for the extended period of nine months, making a total of 81 referred candidates.

Apothecaries' Hall.—The following gentlemen passed their examination in the Science and Practice of Medicine, and received Certificates to Practise, on Thursday, 24th ultimo :—

Marriner, Wm. Herbert Lister, Gunterstone Road, W.
Pilgrim, Hubert Wilson, St. Augustine's Road, N.W.
Urwick, William, St. George's Road, Pimlico.
Vince, Jno. Foster, Wheeley's Road, Birmingham.

The following gentleman also on the same day passed the Primary Professional Examination :—

Heath, Chas. Joseph, of St. Bartholomew's Hospital.

THE CASE OF MESSRS. BOWER AND KEATES.

THE EIGHTH AND FINAL LIST.

The following have sent one guinea each :—T. A. Carter, M.D.; A. E. Cumberlatch, F.R.C.S.; G. Borlase Hicks, Esq.; J. Irving, M.B.; T. J. Maclagan, M.D.; W. Pearse, Esq.; J. B. Story, M.B.; W. L. Underhill, F.R.C.S.

The following have sent half-a-guinea each :—W. Curtis Hugman, F.R.C.S.; G. Knapton, Esq.; C. Latham, Esq.; W. H. Latham, Esq.; A. C. Tunstall, M.D.

The following have sent ten shillings each :—R. Ives, Esq.; R. J. Pye-Smith, F.R.C.S.

The following have sent five shillings each :—W. Grant, M.B.; B. Harvey, Esq.; H. Hick, Esq.; W. A. Maybury, M.D.; M. F. Ryan, Esq.

F. A. Mahomed, R. W. Burnet, } *Hon. Secs.*

APPOINTMENTS.

Apthorp, F. W., M.R.C.S., L.R.C.P.—Medical Officer and Public Vaccinator, Manhood District, Westhampnett Union, *vice* Thomas Dutton, M.D., M.B., M.R.C.P., resigned. Also, Surgeon to Courts "Star" and "Manhood" Ancient Order of Foresters, *vice* Thomas Dutton, M.D., M.B., M.R.C.P., resigned.

Bateman, H. E., L.R.C.P., M.R.C.S.—Resident Medical Officer to the York Dispensary, *vice* E. H. Morgenrood, M.B., resigned.

Beamish, S., M.D.—Medical Officer for the Union Hall Dispensary District, Skibbereen Union.

Bourne, A., L.R.C.P.—Visiting Medical Assistant to the Newcastle-on-Tyne Dispensary, *vice* T. Clarke, M.B., resigned.

Brickwell, J., M.R.C.S., L.S.A.—Medical Officer for the Stoke District of the Eaton Union.

Carr, John A., L.R.C.P. Edin., L.R.C.S. Edin.—To the Kippax District, Tadcaster Union.

Crook, John, M.R.C.S. Eng., L.S.A.—To the Third District, Norwich Union.

Fisher, S. W., M.D.—Honorary Physician in Ordinary to the Brighton and Hove Dispensary, *vice* Dr. Tyler Smith, resigned.

Fowke, F. W., L.R.C.P. Edin., M.R.C.S. Eng., L.S.A.—To the Fifth District, Daventry Union.

Gamgee, Arthur, M.D., F.R.S.—Physician to the Manchester Hospital for Consumption and Diseases of the Throat.

Limont, James, M.A., B. Sc., M.B.—House-Physician to the Infirmary, Newcastle-on-Tyne.

Lucas, Arthur, M.R.C.S., L.S.A.—Medical Officer to Wovenden Parish, Newport Pagnell Union.

Meeham, N., M.D.—Medical Officer to the New Ross Union Dispensary, *vice* P. Mullin, L.R.C.S., deceased.

Mivart, F. C. St. George, M.R.C.S.—Honorary Surgeon to the Western General Dispensary.

Roe, A. D., B.A., M B. Cantab., M.R.C.S.—Clinical Assistant to the Brompton Hospital for Consumption.

Smyth, F. S., L.R.C.P., L.R.C.S.—Honorary Medical Officer to the Royal Kent Dispensary (Brockley District).

DEATHS.

Foote, Gustavus, M.R.C.S., at Kington, Herefordshire, on Jan. 24, aged 59.

Harley, Thomas, M.R.C.S., at The Lawn, Haverstock Hill, on January 27, aged 65.

Pocock, E. W., M.R.C.S., at Mackay, Brisbane, aged 38.

Sinclair, Geo. Murray, L.R.C.P., L.R.C.S., at Ely, Cambridgeshire, on January 23, aged 14.

Wood, Thomas, Surgeon-Major, Army Medical Department, at Enniskillen, on January 26.

VACANCIES.

Ashby-de-la-Zouch Union, Fourth District.—Medical Officer. Area 6,861 acres. Population 6,393. Salary £60 per annum.

Bolton Union, Westhoughton District.—Medical Officer. Area 8,693 acres. Population 13,014. Salary £60 per annum.

Boscombe Provident Infirmary, Bournemouth.—Resident Medical Officer. Salary £60 per annum, with board, &c. Candidates must be duly registered and unmarried. They are prohibited from engaging in private practice. Applications, together with copies of testimonials, to be sent to the Secretary, before February 11.

City of Ely Dispensary.—Surgeon and Dispenser. (*For particulars see Advertisement.*)

Droxford Union.—Medical Officer to the Workhouse. Salary £15 per annum.

Droxford Union, Droxford District.—Medical Officer. Area 12,836 acres. Population 3,382. Salary £55 per annum.

Hearts of Oak Benefit Society.—Consulting Physician. (*For particulars see Advertisement.*)

Huddersfield Union, Horley District.—Medical Officer. Area 2,435 acres. Population 5,070. Salary £16 per annum.

Launceston Union, Second District.—Medical Officer. Area 7,029 acres. Population 1,125. Salary £13 per annum.

Leeds General Infirmary.—House Surgeon. Salary £100 per annum, with board, residence, and washing. Candidates must be Members or Licentiates of a British College of Surgeons. Copies of testimonials to be sent to Dr. T. Clifford Allbutt, the Infirmary, Leeds, on or before February 8.

Malton Union, Hovingham District.—Medical Officer. Area 15,160 acres. Population 2,555. Salary £32 per annum.

Nottingham Borough Asylum.—Assistant Medical Officer. Salary £100 a year, with board, apartments, and washing. Candidates must be duly qualified in Medicine and Surgery, and registered. Applications, with testimonials, stating age, &c., to be sent to the Medical Superintendent, on or before February 16.

Royal Surrey County Hospital, Guildford.—House Surgeon. (*For particulars see Advertisement.*)

APPOINTMENTS FOR THE WEEK.

February 4. Monday.

MEDICAL SOCIETY OF LONDON.—Mr. R. Brudenell Carter will deliver his Third and Last Lettsomian Lecture, subject—"Modern Operations for Cataract."

ODONTOLOGICAL SOCIETY OF GREAT BRITAIN, 8 p.m.—Mr. G. W. Parkinson, Mr. Fredk. Canton, and Dr. W. St. George Elliott, "Casual Communications." The President (Mr. J. S. Turner) will read his Introductory Address.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, 4 p.m.—Prof. W. K. Parker, F.R.S., will deliver his First Lecture "On Mammalian Descent."

ROYAL INSTITUTION, 5 p.m.—General Monthly Meeting.

5. *Tuesday.*

MEDICO-PSYCHOLOGICAL ASSOCIATION, BETHLEM HOSPITAL, 4 p.m.—The following Papers will be read: Dr. Savage, "On Constant Watching of Suicidal Cases;" Dr. Gasquet, "On Some of the Mental Symptoms of Ordinary Brain Disease;" Dr. Herbert Major, "On the Results of the Collective Record of the Causation of Insanity."

PATHOLOGICAL SOCIETY OF LONDON.—Mr. Bowlby, "Sporadic Cretinism;" Dr. Barlow, "A Case of so-called Fœtal Rickets (? Cretinism);" Dr. Lediard, "Epithelioma of the Foot after Injury" (card); Dr. Hale White, "Fibroid Disease of the Heart;" Mr. Batlin (for Mr. Benton), "Carcinoma of Œsophagus;" Sir H. Thompson, (1) "A Growth from the Bladder," (2) "Calculus impacted in a Sac in the Bladder;" Dr. Norman Moore, "Interstitial Disease of Ovary;" Dr. Angel Money, "Spinal Cord of a recent and old Case of Infantile Paralysis;" Dr. Sainsbury, "Malignant Disease of the Mesentery;" Mr. G. Stokes, "Pigmentary Degeneration of the Tongue" (living specimen); Mr. Bowlby, "Dermoid Cyst of the Finger" (card).

ROYAL INSTITUTION, 3 p.m.—Prof. A. Geikie, "Scenery of the British Isles."

6. *Wednesday.*

OBSTETRICAL SOCIETY, 8 p.m.—Dr. Matthews Duncan will show Dr. Auvard's rest; specimens will be shown by Dr. Galabin and Dr. Horrocks. Paper by Mr. Alban Doran, "The Relation of Prolapse of the Vagina to Hernia," illustrated by two pedigrees. Annual Meeting—The President (Dr. Gervis) will deliver the Annual Address.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, 4 p.m.—Prof. W. K. Parker, F.R.S., will deliver his Secoud Lecture "On Mammalian Descent."

7. *Thursday.*

ROYAL INSTITUTION, 3 p.m.—Prof. Pauer, "Music for the Pianoforte," &c.

8. *Friday.*

CLINICAL SOCIETY OF LONDON.—Mr. A. Pearce Gould, "Obliterative Arteritis accompanied by Gangrene;" Dr. Hadden, "Obliterative Arteritis ending in recovery;" Dr. Burney Yeo, "Primary Syphilis with Acute Pyrexia;" Dr. Mansell Moullin, "Thrombosis of Vena Cava;" (living specimens); Dr. Radcliffe Crocker, "Keloid on Chest;" Dr. Stephen Mackenzie, "Acne Variioliformis."

ROYAL COLLEGE OF SURGEONS OF ENGLAND, 4 p.m.—Prof. W. K. Parker, F.R.S., will deliver his Third Lecture "On Mammalian Descent."

ROYAL INSTITUTION, 8 p.m.—Mr. G. J. Romanes, "The Darwinian Theory of Instinct."

9. *Saturday.*

ROYAL INSTITUTION, 3 p.m.—Prof. Morley, "Life and Literature under Charles I."

NOTES, QUERIES, AND REPLIES.

THE HIND FUND.

The following additional subscriptions have been received and paid to the account of the "Hind Fund" at Messrs. Coutts' Bank:—J. D'Arcy Harvey, Esq., Staff Surgeon, R.N., £1 1*s.*; R. W. Ollivier, Esq., £2 2*s.*; H. D. Shepard, Esq., £3 3*s.*; W. H. £5 5*s.*

Subscriptions may be paid to Dr. Richardson, F.R.S. (chairman), 25, Manchester-square; John Tweedy, Esq., F.R.C.S., 24, Harley-street, hon. treasurer; A. J. Pepper, Esq., F.R.C.S., 122, Gower-street; and T. Wakley, jun., Esq., L.R.C.P., 96, Redcliffe-gardens, hon. secretaries; or to Messrs. Coutts and Co., Strand.

THE ROGERS FUND.

The following is the twelfth list of subscriptions:—Jas. Cornwall, Esq., F.R.C.S., Fairford, Gloucestershire, £1 1*s.*; D. B. Balding, Esq., F.R.C.S., Royston, Herts, £1 1*s.*; A. A. Jackson, Esq., Birmingham, £1 1*s.*; W. Pearse, Esq., St. Tadye, Bodmin, £1 1*s.*; M. Partridge, Esq., Coventry, 10*s.* 6*d.*; Jno. Davies, Esq., 91, New North Road, 10*s.* 6*d.*; F. Haward, Esq., Halesworth, 10*s.*; Dr. J. Woodman, Exeter, 5*s.*

COMMUNICATIONS RECEIVED—

Sir Wm. MACCORMAC, London; Dr. J. MATTHEWS DUNCAN, London; Mr. J. HUTCHINSON, London; Mr. E. NETTLESHIP, London; Dr. CLIFFORD BEALE, London; Dr. TIRARD, London; Dr. SHELLY, Hertford; Mr. R. M. GUNN, London; Dr. WILLOUGHBY, London; THE HON. SECRETARY, PARKES MUSEUM, London; Dr. G. H. FOX, New York; THE SECRETARY, APOTHECARIES' SOCIETY, London; THE HON. SECRETARY, ODONTOLOGICAL SOCIETY, London; Messrs. CASSELL AND CO., London; Mr. EDMUND OWEN, London; THE PRESIDENT, DR. BARNARDO'S HOME, London; Mr. A. EVERSHED, London; THE SECRETARY, HOSPITALS ASSOCIATION, London; Dr. GEORGE COATES, London; Dr. CHOLMELEY, London; Mr. W. J. MILLES, London; THE SECRETARY, ASSOCIATION FOR TRAINING THE DEAF AND DUMB, London; Dr. HERMAN, London; Dr. J. OWEN, London; Mr. P. CHALMERS, Wimbledon; THE SECRETARIES, HUNTERIAN SOCIETY, London; THE HON. SECRETARY, CLINICAL SOCIETY OF LONDON; Dr. ALEXANDER, Liverpool; Mr. A. M. SHEILD, London; THE REGISTRAR-GENERAL FOR SCOTLAND, Edinburgh; Dr. R. N. WOLFENDEN, London; Mr. J. B. SCRIVEN, London; Mr. WYNTER BLYTH, London; THE HON. SECRETARY, PATHOLOGICAL SOCIETY OF LONDON; THE SECRETARY, UNIVERSITY COLLEGE, Liverpool; Dr. T. DUTTON, Sidlesham, Chichester; Messrs. STREET BROTHERS, London; Mr. T. M. STONE, Wimbledon; THE HON. SECRETARY, BRITISH MEDICAL BENEVOLENT FUND, London; THE MANAGER, GULCHER ELECTRIC LIGHT CO., London; Mr. WICKHAM BARNES, London; HON. SECRETARY, OBSTETRICAL SOCIETY, London; THE SECRETARY, MEDICAL SOCIETY OF LONDON; Mr. BECHER, London; THE SECRETARY, ROYAL INSTITUTION, London; Dr. MARTIN, Manchester; HON. SECRETARIES, THE BOWER AND KEATES CASE, London; HON. SECRETARY, THE HOME HOSPITALS ASSOCIATION, London; Mr. J. BELLAMY, LOCAL GOVERNMENT BOARD, London; THE EDITOR, SANITARY ENGINEER, London.

BOOKS RECEIVED—

The Parent's Note-Book, by A. Dunbar Walker, M.D., C.M.—Bedside Urine Testing, by G. Oliver, M.D.—Illustrated Medicine and Surgery, Vol. II., No. 4.—Orthopædic Apparatus, by F. Gustav Ernst.—Sir Lyon Playfair and Sir Charles W. Dilke, by William White.—Scrofola e Sifilide Studio del Dott, Sebastiano Giovannini.—The Pedigree of Disease, by Jonathan Hutchinson, F.R.S.—Pharmahologie, von Dr. C. MODERN OPERATIONS FOR CATARACT.

THE LETTSOMIAN LECTURES DELIVERED AT THE MEDICAL SOCIETY OF LONDON.

By R. BRUDENELL CARTER, F.R.C.S.,

Ophthalmic Surgeon to St. George's Hospital.

LECTURE III.

IT is a maxim of political economy that every learner must spoil a portion of raw material; and this maxim, in its application to the old method of cataract extraction by the flap, was rendered by the saying which Beer is believed to have originated, to the effect that every beginner would destroy a hatful of eyes before he cured one. In any literal sense, this must always have been a gross exaggeration, but still it is not the least valuable result of modern improvements that they tend to place the beginner and the expert more nearly upon a level than was formerly the case. In flap extraction, before fixation by forceps was introduced, and when the eyeball was only steadied, and supported against the knife, by the tips of the index and middle fingers of the surgeon, resting one above and the other on the nasal side of the cornea, nothing but practice could give the mingled lightness and firmness of touch which were required in order to afford security against two dangers; the first being that the support would be insufficient, and that its insufficiency would permit rotation of the eye before the knife, and consequent displacement of the section from its right position; the second, that the finger pressure would be too decided, and that it might cause the premature expulsion of the lens, followed by more or less of the vitreous body. Fixation by forceps was introduced, I believe, by the late Mr. Poland, and was applied by him to flap extraction with considerable advantage; but I am not aware that his example was at all extensively followed, and it was not set until shortly before the new methods were devised. Of these, as we all know, forceps fixation forms an essential part; and for this reason, as well as on account of the altered character of the section, it is not too much to say that every young surgeon, who possesses adequate anatomical knowledge, fair mechanical dexterity, and some practical acquaintance with the densities and resistances of the textures especially concerned, should be able to perform even his first cataract operation upon the living eye with a creditable amount of success. The chief advantage of experience consists less in its conferring mere manual dexterity than in its conferring the power of at once perceiving the nature of any difficulties or complications which may arise in the course of an operation, and the best manner of dealing with them; in its conferring, in other words, an immunity from being taken by surprise, and a readiness at any moment, and almost instinctively, to do what ever any deviation from the normal course of things

may require. I may add that, in watching young surgeons, few things have struck me more than their frequent unwillingness to avail themselves of the most admirable opportunities for leaving off; so that we sometimes see the results of a well-performed operation imperilled, or even lost, by too great solicitude about the last morsel of cortical substance, or about the relations of the iris to the angles of the wound. Both are highly important, but something must occasionally be sacrificed in regard to them in order to avoid expulsion of the vitreous body by reflex contraction of the ocular muscles. The more an operation is prolonged, the more risk there will be that such reflex contraction may occur.

In speaking of the accidents incidental to early operation, I do not intend to refer to any which are only rendered possible by the absence of adequate surgical dexterity, but to limit myself to those which must sometimes happen to every operator; and among these, as a matter of possible, although of extremely rare, occurrence, we must place injury to the lens in the course of the preliminary iridectomy. Every ophthalmic surgeon of experience has seen cases of traumatic cataract after iridectomy, either in his own practice or in that of others; and in some of these the operator would have no consciousness of having wounded the capsule. It is quite possible that a delicate capsule may sometimes split during iridectomy, without having been touched by either knife or forceps; and there are at least two other ways in which the accident may occur. The speculum will sometimes be jerked out from between the lids by muscular spasm; and, if this should happen while the knife is in the anterior chamber, the surgeon will be fortunate if he succeeds in withdrawing it without the infliction of any undesigned injury. In other cases, even when under apparently profound anæsthesia, the patient will sometimes make an unexpected movement at a critical moment of the operation. I have known a sudden and violent sneeze occur when the knife was in the eye, this sneeze being clearly reflex, and analogous to that which is produced, in some forms of photophobia, by exposure of the cornea to light. However rare such accidents, it is necessary to be prepared for them, and to take thought beforehand of the course of action which they will require.

If the surgeon is conscious of having wounded the lens in the performance of iridectomy, extraction must be proceeded with at once. A serious difficulty may here arise from the circumstance that the wound made for the iridectomy will neither be long enough to afford easy exit to the lens, nor be situated in the most favourable position for the purpose. The iridectomy wound, if made with a narrow knife, will be almost concentric with the corneal margin; if made with a broad knife, its extremities will even advance somewhat upon the corneal tissue. The mechanical difficulties of prolonging it in a suitable direction with the same knife would be great in either case, and would probably be insuperable in the latter. The best method of proceeding is to withdraw the knife, if that has not been done before the accident is discovered, to shift the fixation forceps to the left hand angle of the wound, and then to extend the incision, from the right hand angle, with the side edge of a narrow parallel-sided knife, set at an angle upon its stem, and furnished with a rounded and blunt extremity. Such a knife may be introduced into the anterior chamber, and then made to cut laterally to whatever extent may be desired, while the narrowness of its blade allows the left hand edge to be directed forwards, so as to turn the right hand edge slightly backwards, and thus keep the new portion of the incision in or beyond the corneal margin. It must be remembered that such an incision, after all, will not be in the most favourable position and direction for the exit of the lens; and the difficulties which might hence arise must to some extent be provided aginst by making it of greater length than would be necessary if it were better planned. If a piece of the iris has not yet been excised, the excision should be made to the full length of the wound; and, if an iridectomy has been made through the original small opening, a second piece of iris should be removed to the extent of the new one. It is only by this precaution that future entanglement can be guarded against. Notwithstanding the wound of the anterior capsule, the cystitome must be employed to secure that the division is sufficiently extensive, especially in the equatorial region, and then the extrusion of the lens may be attempted by very careful pressure. If it does not advance at once the use of a traction instrument becomes imperative. If the difficulty depend only upon mal-position and reluctant opening of the wound, it will be best to use Pagenstecher's scoop, the tip of which may be insinuated for a short distance behind the nucleus, and made to open the wound by holding back its posterior margin. Slight pressure with the fixation forceps will then frequently be followed by an advance of the lens; but, when the cause of retardation is in the adhesion of the nucleus to the cortex, it is best to lay aside the spoon and to use a fine loop devised by Dr. Bell Taylor, and called by him a "vectis." This loop, which occupies less room than any other traction instrument, and which obtains a very secure hold, should be glided through the posterior cortex to the inferior margin of the lens, and then bedded in the posterior surface of the nucleus by lifting this against the cornea, after which it may be used for extraction, the further margin of the loop being kept well up against the cornea as the bulk of the nucleus passes through the section. The speculum should then be removed, the lids closed, and covered with a supporting pad, while the operator waits two or three minutes for the action of the aqueous humour upon the residual cortex. After this time the lids may be reopened, any apparent cortex removed by rotatory friction through the lower lid and by gentle pressure on the cornea, or even brought away by the cautious introduction of a curette. When no more can be done in this direction, either because no more cortex is visible, or because loss of vitreous occurs or seems to be probable, the lids must be closed by the ordinary bandage. In all such cases, a certain amount of iritis must be expected; but, in many of them, it can be kept within bounds by careful and well-directed treatment.

A troublesome complication of an iridectomy, which, perhaps, can hardly be described as an accident, is the occurrence of an unusual amount of hæmorrhage into the anterior chamber. This is especially prone to happen in cases in which an immature cataract is combined with an early stage of glaucoma, or even with the increase of tension which may be produced by an increase in the bulk of the lens. However arising, increased tension produces passive congestion of the intra-ocular structures; and hence the excision of a portion of iris may give rise to a more free and more prolonged bleeding than is usual. In such a case, the blood may generally be evacuated by carefully introducing a spatula or curette within the lips of the wound, but it is apt to re-accumulate, and to fill the available space in the anterior chamber. When this is so, it frequently acts as a foreign body during the period of healing, produces protracted pain and irritation, and sometimes sets up actual iritis. Such occurrences always retard the period at which extraction can safely be undertaken, but they are less serious in their import than an insidious form of iritis which sometimes follows the iridectomy without manifest cause, and which can only be attributed to some septic influence or to some defect of nutrition. The iritis consequent upon blood irritation will generally yield

to treatment; and, as there should be no intra-ocular bleeding at the time of the final operation, there need then be no cause adequate to the reproduction of the effect. The apparently spontaneous form, on the other hand, will probably reappear after extraction; and this probability casts grave doubt upon the propriety of carrying the treatment farther, until the cataract has made such progress that the state of vision does not admit of being altered for the worse. In other words, a risk, almost as great as the risks incidental to flap extraction, takes us back to the practice of the time when flap extraction was habitually performed.

In dealing with cases of somewhat heightened tension, whether this be distinctly glaucomatous, or due to enlargement of the lens, it is necessary to diminish both the tension and the intra-ocular congestion which attends it, by the previous instillation of eserine. We must not then be content with a single application, for the mere purpose of obtaining a contracted pupil; but the drug should be applied regularly, say night and morning for four or five days, as a preliminary to the performance of the iridectomy. By this means, we shall frequently succeed in obviating the tendency to hæmorrhage which might otherwise produce embarrassment or even disaster. In all such cases, moreover, the object of the iridectomy will not merely be to destroy the continuity of the sphincter of the pupil, but also to diminish tension in a permanent manner. For this purpose the piece of iris excised must be of considerable magnitude, and it must be taken off quite close to the ciliary border.

When a sufficiently long time has elapsed since the performance of the iridectomy, the propriety of proceeding with the extraction must be considered. We may divide the unfavourable cases into two classes—those in which there is a tendency to sloughing of the cornea, and those in which there is a tendency to plastic iritis. The first-named risk, that of sloughing, is most marked where the cornea is thin and under nourished; a state which may often be inferred from an inelastic condition of the skin of the hands, and from the absorption of subcutaneous fat; and of which we obtain strong evidence when, at the time of the iridectomy, the cornea collapses or falls into wrinkles as soon as it loses the support of the aqueous humour. It was in cases of this class that Mooren obtained his most conspicuous successes by preliminary iridectomy; and they call for the adoption of his method even when the cataract is mature. I have, at present, in St. George's Hospital, a patient who admirably illustrates the value of the proceeding. He is an old and feeble man, whose left eye was destroyed long ago by disease or injury, and who was admitted with mature cataract and extreme conical cornea of the right eye. At the time of the iridectomy, his cornea fell into folds, and seemed to have scarcely an appreciable thickness; but, both then and after the subsequent extraction, the section healed readily and completely. In such cases, it is my usage to shorten the interval between the operations. There is, practically, little or no fear of iritis; and, I think, the cornea has a better chance of survival, after the second and more extensive incision into the eye, if the vascularity incidental to the healing of the first incision has not yet disappeared, so that the wound falls into a region of artificially increased blood supply. At the same time, it is of course desirable to limit the extent of the second incision as much as the size of the nucleus will permit, even if we have to assist the escape of the lens by the "schlitten-manœuvre," or by the use of some form of traction instrument. The remaining of a small portion of cortex within the eye is of less importance in these cases than in many others. It seldom causes much irritation, and is often absorbed without trouble, or at most with the effect of leaving capsular films within the eye, which will subsequently require to be torn by the use of a needle or needles. It must be admitted, without hesitation, that the modern forms of extraction, whether on mature or immature cataracts, whether performed as a single operation or divided into two, are followed, more frequently than flap extraction, by secondary films which require a subsequent operation for their removal. I do not regard this as a disadvantage: for the facts might, perhaps, be fairly stated by saying that, in many of the eyes which would have perished under the old method, the new one requires a secondary but trivial operation in order to attain a completely good result.

Whenever the risks of the final extraction seem to lie entirely on the side of plastic iritis, it is desirable to extend the interval between the two procedures rather than to shorten it, and to insure that the eye has, so to speak, forgotten the first before it is called upon to submit to the second. The greatest probability of iritis is present in the cases in which it has followed the preliminary iridectomy, otherwise than as a result of irritation from blood in the anterior chamber. A somewhat plethoric habit, a tendency to the lithic acid diathesis, and generally any imperfection or inadequacy in the performance of the renal function, are conditions which should be looked upon with grave distrust, and which should be amended, as far as any emendation may be possible, before either the iridectomy or the final extraction can be prudently undertaken. I believe there are many cases in which the prospect of success are enormously increased by two or three weeks of careful medical treatment as a preliminary; such treatment usually comprising a restricted diet, the moderate use of alteratives and purgatives, and attention to the action of the skin.

Whenever the time for the extraction of the lens arrives, there are, of course, certain risks inseparable from the actual conduct of the procedure, although these are, I think, both less numerous and less formidable than those which attend upon extraction performed in immediate sequence to iridectomy. The worst accident which can befall during cataract extraction is hæmorrhage from the rupture of a vessel in the choroid, hæmorrhage which necessarily produces detachment of the retina, and which at once extinguishes all hope of the restoration of sight. When iridectomy has been performed at an earlier period, such hæmorrhage is very unlikely to occur, since the choroidal vessels, even if diseased and weak, will have learnt to accommodate themselves to a diminished amount of support, and will be little likely to give way. I have seldom seen this accident occur in any form of modified linear extraction, never when the iridectomy and the extraction were separated by an interval of time.

The only remaining accidents which need be noted are loss of vitreous, and failure to remove the lens. I once saw a case in which the surgeon had made an incision insufficient for the exit of a very large and hard nucleus, which became engaged in the wound, but which refused to advance beyond a certain point without the exercise of more pressure than it seemed prudent to employ. The operator, therefore, determined upon the use of a traction instrument, and laid down his pressure spoon to take up a Pagenstecher's scoop. He attempted to insinuate this between the posterior aspect of the nucleus, and the posterior margin of the wound; but with the result that the nucleus returned into the eye and passed out of sight into the vitreous, a considerable quantity of which escaped. The operator made a dive after the lens, but could not find it, and had no choice but to close the eye. A day or two later, the nucleus reappeared in the pupillary region, the wound was reopened, and the nucleus was removed by a scoop without the slightest difficulty. There was no acute reaction, but the eye

*

became the seat of an insidious form of low inflammation, under which it ultimately underwent total wasting.

A more common cause of loss of vitreous is from spasm of the external ocular muscles, or from the strain incidental to vomiting. About a year ago, I performed an extraction which, up to the moment of completion, was all that I could desire. The cataract was fully mature, and the iridectomy had formed part of the procedure. The pupil was perfectly clear, and I was just taking a last look at the eye prior to the application of the bandage, when the globe was visibly compressed by contraction of the recti, the wound gaped, and a large quantity of vitreous was expelled. In such a case, manifestly, the patient is beginning to recover from the anæsthetic, and comes into a state in which volition is still suspended, and in which the wound becomes an excitant of reflex spasm. In another case, after the operation had been satisfactorily completed, the bandage applied, and I had left the house, vomiting commenced, apparently from the effects of the anæsthetic, and continued throughout the day with great severity. The patient was under the care of her usual medical attendant, who did not send for me; and, when I went in the evening, I found that the bandage had become displaced, and that the eyeball had been almost emptied by the straining. I have no doubt that he did all that was possible to arrest the vomiting; and, although I should have liked to reapply the bandage in such a manner as to secure effectual external support, it is highly probable that the mischief may have been done almost in the first effort, and that, after this, all such support would have been in vain. These two cases seem to me to furnish admirable illustrations of what may fairly be called "accidents," occurrences which can neither be foreseen nor guarded against, and by which the reasonable expectations, both of the patient and of the surgeon, may be frustrated without fault on the part of either.

A more ordinary form of loss of vitreous is when it occurs during the course of the extraction, either as a result of spasm, or from mere weakness of the hyaloid membrane, which, there can be no doubt, is much more frail, and more prone to yield in some eyes than in others. Great risk of rupture of the hyaloid, even when of normal firmness, is attendant upon a condition of imperfect anæsthesia, in which the natural tendency of the superior rectus muscle to roll the eye upwards, and to remove it out of the way of injury, is not abolished. In such a condition, the operator is compelled, at every step, to roll the eye downwards by the forceps, in order to obtain access to the region in which his proceedings are conducted; and the result is that the hyaloid is made to bulge towards the wound by the opposing traction of the forceps and of the muscle, and that it is exposed to manifest danger of giving way.

The occurrence of loss of vitreous, however occasioned, calls upon the surgeon for prompt decision with regard to the course which should be pursued. We may take, as three typical conditions, the cases in which the loss occurs after the whole of the nucleus and cortex has been removed, the cases in which the loss occurs prior to the removal of either, and the cases in which the vitreous follows the nucleus, when there is still cortex remaining within the eye.

In cases of the first class, when everything has been romoved, and when loss of vitreous follows the last step of a completed operation, there is nothing to do but to apply the usual bandage with as much rapidity as possible, and with something more than the usual degree of firmness. The prognosis, in such a case, will depend almost entirely upon the amount of the loss. If it be but small, the case will usually do as well as if it had not occurred; but, whenever the amount is large, ths eye is apt to be attacked by slow and insidious inflammation during or subsequent to the healing process; and, with few exceptions, the sight obtained is at best but very imperfect. The lost vitreous is not replaced by new material of the same kind, but only by a serous fluid, often of incomplete transparency, and liable to undergo fluctuations in quantity, generally on the side of diminution, which lead to recurring subnormal tension, and to many disturbances of the ocular circulation and nutrition consequent thereupon. I have seen several instances in which, after a large loss of vitreous, the immediate visual result was very fair, but in which vision was not long retained.

When loss of vitreous occurs prior to the extrusion of the lens, the first care of the operator should be to see that anæsthesia is complete. If it should not be so, if there should be any action of the recti muscles, or of the orbicularis, the speculum should be gently removed, and the closed lids covered with a sufficient pad of cotton wool, retained by manual support, until more of the anæsthetic has been administered. As soon as the muscles are brought into repose, the speculum should be re-inserted or the lids kept apart by an assistant, and the surgeon should at once remove the nucleus, and as much of the cortex as possible, by some form of traction instrument, generally either Pagenstecher's spoon or Taylor's vectis. If the muscles continue perfectly quiet, he may even follow portions of cortex with a smaller spoon or curette; but this should seldom be done at the cost of further loss of vitreous. The curette or spatula may be used to insure complete replacement of the iris, and proper adaptation of the conjunctival flap; and then the great object should be to get the lids closed and supported as quickly as possible.

In conditions intermediate between those last mentioned, when the vitreous follows the nucleus out of the eye, leaving some portion of the cortex behind, the surgeon is called upon to take into consideration three principal factors; namely, the amount of residual cortex, the amount of the actual and threatened loss of vitreous, and the proneness or otherwise of the patient to plastic inflammation. It need hardly be said that, in immature cases, the precise amount of cortex is difficult to estimate, although the surgeon, before undertaking extraction, should always obtain as exact a knowledge as possible of the thickness of the still transparent cortical layer. Even when this has been done, it must always be difficult to feel sure, at the moment, how much of a practically invisible material remains within the eye. The second element, the amount of actual or probable loss of vitreous, is far more easily ascertained or estimated. In some cases the first loss is a sort of gush or outburst, forcibly expelled by contraction of the recti muscles, while in others it is little more than a leakage, the result of rupture of the hyaloid without muscular spasm. In some cases the vitreous will be liquid, so that it can flow away, in others it will preserve its natural almost gelatinous consistence, and will only leave the eye with difficulty. The decision whether to close the eye, or to persevere in attempts to remove the whole of the cortical substance, must be mainly governed by considerations based upon these respective conditions, the general principle being that cortex must be removed as completely as possible, but that endeavours in this direction must not be prolonged at the expense of a considerable loss of vitreous which might otherwise be retained. The greater the assumed tendency of the patient towards iritis, the more important does the complete removal of the cortex become; but, even when this tendency is strongly marked, I am not aware of any facts which connect the occurrence or the intensity of the inflammation with the quantity of the residual irritant. My experience is rather in the contrary direction; for some eyes are very intolerant of

residual cortex, while others are very tolerant of it; and, when we consider that, in cases of the former kind, the actual quantity appears often to be increased by cell-proliferation, it must be probable that a small amount may do nearly or quite as much mischief as a large one. In patients in whom I consider iritis probable, therefore, I am extremely careful to remove the whole of the cortex when I can; but even in these, and especially in others, I do not think the prospects of a good issue are to be increased by persevering endeavours to take out as much as possible, when vitreous is escaping, and when some portion of the cortex must manifestly be left behind. I am always more disposed to close the eye, to trust to treatment for the control of inflammation, and to a subsequent operation for the displacement or division of any films which the inflammation may leave behind.

The various manipulations to which I have referred, as being generally or occasionally necessary, are manifestly much more easy of accomplishment when the patient is fully under the influence of an anæsthetic, than when this important condition is not fulfilled; and my hearers will have observed that I have more or less assumed the employment of an anæsthetic throughout. More than once, however, since the time when these agents were introduced, special objections to their being employed in cataract extraction have been advanced; and one recent writer has been so emphatic in his condemnation of them that, differing from him as I do, I have thought it right to refer to this part of the subject, and to say exactly what is on my mind. I have had considerable experience on both sides of the question, for my earlier cataract operations, by flap extraction, were all done without an anæsthetic; while of late years I have employed one almost, if not quite, invariably. I believe, in the first place, that the improved methods of operating are mainly due to anæsthetics, and would not have been brought to their present perfection without them. It would certainly not be practicable, in a large proportion of conscious patients, to plan and execute an incision, within very accurately defined limits, at the summit of the cornea; for the simple reason that the instinctive tendency of the superior rectus to roll the eye upwards, and to remove it out of the way of injury, would frequently be too strong to be resisted; while, if this tendency were overcome, against the efforts of the muscle, by forceps traction, there would be frequent laceration of the conjunctiva, and there would be frequent loss of vitreous, at quite an early period of the operation, from rupture of the hyaloid by the struggle between the forceps and the muscle, a struggle which may even now be witnessed, and which is not seldom attended by hurtful consequences, in cases in which the anæsthesia is incomplete. Still less would it have been possible, without the passive eye afforded by an anæsthetic, to carry out the series of almost experimental operations, of slight variations in the position and magnitude of the section, of which the procedure that I have endeavoured to describe is the final outcome; so that, without anæsthetics, I do not believe that either the broad lines of the operation could have been successfully defined, or that those lines could have been strictly adhered to in practice. Against the great benefits of freedom from pain, from apprehension, from hurry, and from restlessness of the eye, there is, according to my experience, only a single counterbalancing disadvantage, namely, the harm which may possibly arise from obstinate vomiting. I have only seen one instance, already referred to, in which the effects of such vomiting were destructive; I have seen many in which vomiting of moderate severity has been productive of no ill result whatever.

I have, however, seen accidents, and those of a serious character, caused by attempts to operate when the effect of an anæsthetic had been insufficiently produced, or had to some extent passed away. I have already mentioned extrusion of the vitreous as thus arising; and I think it may be said, generally, that an imperfect anæsthesia is as bad as none at all. There certainly is a stage in which there is no consciousness of pain, but in which the liability to reflex spasm is intact, and is entirely removed from the control of the volition. Such a state occurs when anæsthesia is as yet incomplete, and again when it is beginning to pass away; and it teaches that the administration of an anæsthetic for operations upon the eye is a matter not to be lightly undertaken, but one which requires to be guided by no small amount of skill and of practical knowledge. A condition in which it would be possible to amputate without the knowledge of the patient would often be insufficient for the performance of an eye operation, a proceeding in which the primary object to be attained is not so much immunity from suffering, as immunity from muscular contraction. I may say at once, that I believe there are some persons in whom the state of quiescence desirable for an eye operation is not to be attained without peril, and in such cases the administrator should be prepared to warn the operator of the difficulty, and the operator, in his turn, should be prepared to act with great promptitude in the few moments of profound repose which may sometimes be obtained.

The selection of the anæsthetic agent is a matter of considerable importance. But for its liability to occasion death, there is nothing which combines so many advantages as pure chloroform, but this liability is enough to neutralise them all. Chloroform kills, in round numbers, about one in every three thousand of those to whom it is administered; and there ought to be no deaths in ophthalmic surgery. If experience has made anything certain, I think it is that the fatal accidents from chloroform have occurred in the very cases in which there was no reason to anticipate them. I sometimes use it when I am short-handed, and when the administrator is comparatively unskilled in the use of anæsthetics, because I think it is then as safe as any other, and is more easy of administration, and more likely to be effectual than any other. Excepting in such conditions, and in the case of young children, in whom the danger to life from its effects seems to be almost infinitesimally small, I think it ought to be banished from surgery. Pure ether is an admirable and very safe anæsthetic, but it requires a boldness and freedom of administration which are only attained by practice, and, if imperfectly given, it is utterly inefficient for the purposes of the ophthalmic surgeon. Moreover, it is apt, especially if tardily and ineffectually administered, to produce a free secretion of bronchial mucus, which occasions troublesome and unrestrained coughing, and sometimes leads to sickness. When nitrous oxide gas is administered as a prelude to ether, the secretion of mucus is less likely to be troublesome, but a great amount of venous congestion is always produced, and the tissues become so gorged that every incision bleeds freely. In the performance of iridectomy, under gas and ether, we not only have an unusual amount of bleeding from the conjunctiva, or from the vessels of Schlemm's canal, if these should be divided, but we also have a large effusion of dark and unoxidised blood into the anterior chamber from the cut edges of the iris, and this blood, as already incidentally mentioned, is prone to act as a foreign body, and to exite troublesome and possibly very injurious iritis.

Judging from my own opportunities of observation, I am inclined to believe that the best anæsthetic, for general use in ophthalmic surgery, is the mixture which is commonly known as A.C.E., and which contains one part by measure of absolute alcohol, two of chloro-

form, and three of ether. A mixture of ether and chloroform was long ago suggested by very obvious considerations, but it was not found to succeed well in practice. It was merely a mixture; and, as its ingredients were of different degress of volatility, they evaporated unequally, and left the administrator in a state of uncertainty with regard to the proportion of each which might be left in his inhaler at any given time. The addition of alcohol provides a solvent for the other two, and they evaporate together. The mixture should be administered freely, from a flannel or felt cone, and the desired effect should be produced as rapidly as possible. To prolong the administration of an anæsthetic, of whatever nature, to give small doses timidly, with frequent admissions of air between them, is, I believe, the most certain method of producing disaster from its imperfect operation. By disaster I do not mean death, but incomplete anæsthesia, prolonged struggling, muscular spasm, and probably eventual sickness. The cases which do best are those in which the effect is rapidly produced, and in which it is as rapidly recovered from. It would be foreign to my subject, and beyond the limits of my time, to attempt to describe the precautions with which the use of every anæsthetic should be surrounded, but I may add that one advantage of the A.C.E. is the ease with which the mixture can be replaced by pure ether in cases which seem to call for such a substitution. When this substitution is made, moreover, the patient being already narcotised by the A.C.E., the pure ether has little tendency to produce the excessive bronchial secretion which constitutes one of the difficulties of its employment from the first. I need only add, that, more especially in cataract operations, the ophthalmic surgeon who cares for the welfare of his patients, or for his own reputation, will not lightly commit the anæsthetic to strange or unskilled hands, but will insist upon obtaining the aid of an administrator of skill and experience, who knows the special requirements of eye work, and who is capable of relieving the operator from the duty of thinking at all about the anæsthetic or its effects. The administrator should then assume entire responsibility for his share of the proceedings, and the surgeon should await his permission to commence.

I have left myself but short time in which to speak of remaining topics of great importance, such as the complications which may arise after an operation, and the treatment which they may require. Such subjects, however, can only be discussed within short limits in the most general way, because no two cases will present quite the same conditions or peculiarities, and each must be a study in itself.

One of the most troublesome of these complications, and not an uncommon one, is inversion of the lower eyelid by muscular spasm. In old people the skin covering the lower lid is often lax and distensible, and opposes no resistance to the action of the orbicularis. The surface of the eye is uneasy from the wound, and the orbicularis comes into constant reflex action. The result is that the lower lid becomes completely canted over, its margin tucked down within the retro-tarsal fold, so that the eyelashes rest in contact with the globe, where, by the irritation they excite, they provide for the continuance of the displacement. This condition never fails to produce much superficial irritation, which, if neglected, leads on to iritis, so that the position of the lower lid must always be carefully looked to, and any tendency to displacement must be remedied without delay. All that is necessary in this direction may be accomplished by contractile collodion, if only it be effectually applied; but so much depends upon the fulfilment of this condition that the application should never be committed to any but thoroughly trustworty hands. Much of the collodion sold under the name is not really contractile; and the surgeon should always test it by applying a drop to the back of his own hand, and should not use it for the patient unless, in the act of drying, it pulls the skin into strongly marked wrinkles. When satisfied on this point, the next thing is to draw the lower lid well downwards and away from the eye, and thoroughly to dry its cutaneous surface, to which, otherwise, the collodion will not adhere. The collodion should then be painted on with a camel's hair brush, not too large, which must be carried quite up to the ciliary margin of the lid, along its entire length, so that the collodion film comes into contact with the bases of the lashes, but does not pass upon the free lid margin within them. The application should be liberal in point of quantity, and should extend well downwards upon the cheek; but the most important point is that it should go up high enough. If it does not cover the upper portion of the lower lid, this upper portion will become tucked in as before, notwithstanding a patch of collodion below it. The lid should be held down until the drying of the film, which should occur within a minute or so; and, in the meanwhile, any overflow of tears should be arrested by a morsel of absorbent cottonwool. The film once dry, a little almond oil may be brushed over it, and then it will scarcely be affected by lacrimation. As soon as the surgeon has satisfied himself that the lid is completely commanded, and that no attempt to close the eye can again invert it, the ordinary dressing may be applied, and the collodion film will generally require to be peeled off daily, and renewed with the same precautions as before. I believe it is only to neglect of these precautions, or, in other words, to inefficient application, that its supposed failures have been due. In any case, however, where the close personal supervision of the operator cannot be obtained, it is better to proceed at once to a more radical plan of treatment, which cannot fail, and which consists in the excision of a strip of skin and muscle from the eyelid, parallel with its margin. The piece excised must not be too wide, lest permanent deformity be produced. It should be taken from close to the lid margin, and the wound should be united by a single fine suture. Where lid inversion has already done mischief, the bleeding from the skin excision seems to be sometimes serviceable. The state of inversion is one with which it will not do to temporise; for I believe it is never recovered from spontaneously, and that it never fails to do harm. Dr. Bell Taylor has proposed to treat it by the application of a pair of flat bulldog forceps, which pinch up and retain a horizontal fold of skin, but I have no experience of this method, which would certainly, I think, be more painful than excision. It will generally be desirable, whenever lid inversion is at all threatened, although not present in a manner sufficiently declared to call for interference, to leave off a bandage if the state of the eye will at all permit. The heat and pressure which a bandage produces seem to be predisposing causes of the exaggerated action of the orbicularis.

Practically speaking, the only other complication which can follow extraction is the occurrence of internal inflammation; and as this, in whatever structure it originates, owes its chief importance to the participation of the iris, it may conveniently be called iritis. We may say of it that it is least severe, and least likely to be attended by permanent ill-consequences, when it is excited by hæmorrhage into the anterior chamber, or by inversion of the lid, and that it is most likely to be hurtful when it is excited by the presence of retained cortex, especially if this should have undergone manifest proliferation and increase. In such circumstances, the inflammation is apt to assume a septic character, to extend to the ciliary body and choroid, and to terminate in wasting of the eye.

When iritis occurs in any severity, the treatment

must be conducted on the general principles of relieving pain, supporting strength, diminishing vascular action, and relieving tension. In these, which are practically traumatic cases, occurring in old people, mercury, I think, is seldom or never indicated. A leech, or two leeches, applied about an inch from the margin of the orbit, and repeated according to circumstances, the application of moist compresses, or of fomentations, at a temperature governed by the sensations of the patient, the performance of paracentesis of the anterior chamber, by which, together with the aqueous humour, softened cortical matter may often be removed from the eye, and the prompt division of any organised films, which may form a barrier between the anterior and the posterior chamber, will constitute the chief points which require attention. In any case in which the two chambers become completely separated, there is no time to be lost; for the accumulation of fluid which occurs behind the barrier, will soon prove permanently destructive to vision. It is useless, generally speaking, to rely upon any small opening, and the only trustworthy method, is by the free division of the tissues concerned, which, generally speaking, consist of iris, the posterior lenticular capsule, and more or less lymph which has been effused upon or between them. The plan which I find most effectual is to divide the whole of these structures, generally in a horizontal direction, by a pair of scissors which were devised, for this especial purpose, by Mr. Foveaux, formerly of the firm of Messrs. Weiss and Son.

Even when the iritis is not severe, there is generally, after the extraction of immature cataracts, some indication of its presence; and whenever it occurs, in however slight a degree, the pupil is certain to be more or less occluded, by films sometimes of a very delicate character. In some of these cases, it will be sufficient to divide the films by Sir William Bowman's elegant method, by the simultaneous use of two needles; but in many, I think the use of the scissors is to be preferred, in a direction downwards, and that it is better to make also a rather free division of the lower part of the iris. By following this plan, all risk of future traction upon any part of that membrane is finally set aside.

The comparative frequency with which pupillary films require treatment in the modern operations for cataract, and especially after operations for the removal of cataracts which are not fully mature, must not, I think, be regarded entirely as a disadvantage. All operations for the removal or division of films, whether by needles or scissors, divide also the posterior capsule, and afford free communication between the aqueous and the vitreous chambers. The presence of this communication is found, in practice, to afford great security against the occurrence of secondary glaucoma.

I have now, Sir, although in a very fragmentary and imperfect manner, endeavoured to give such a sketch of the chief features of modern cataract operations as the time at my disposal would allow; and it only remains for me briefly to recapitulate the conclusions which I have ventured to set forth. They are, that the performance of iridectomy as a preliminary operation, and the subsequent employment of a comparatively small section through the tunics of the eye, have combined to render the extraction of cataract a more simple, and hence a more frequently successful operation, than it has been at any previous period of surgical history; and that the improvements thus effected have enabled surgeons to deal with comparatively immature forms of the affection, and to rescue from impending blindness many of those who, only a few years ago, would have been left unaided until blindness was complete. These great boons to humanity have not been without their drawbacks, and the extraction of cataracts at an early date is still beset with risks of a peculiar kind, which require, in order that they may be obviated, the possession and the employment of all the resources of the healing art. These risks, however, are such as may properly be incurred in the presence of any adequate inducement; and there are very few people in whom the approach of cataract produces incapacity for the ordinary work or the ordinary amusements of life, in whom it would not be justifiable, with one eye at least, to take steps for their speedy relief. It only remains that I should tender my thanks to you, Sir, and to the Fellows of the Society, for the great indulgence, patience, and kindness, with which my humble efforts have been received.

PRACTICAL NOTES ON THE ORDINARY DISEASES OF INDIA, ESPECIALLY THOSE PREVALENT IN BENGAL.

By NORMAN CHEVERS, C.I.E., M.D.,
President of the Epidemiological Society of London.

(*Continued from page* 78.)

Elephantiasis.

This is a disease which, in its full development, comes within the domain of the surgeon. Its most recently ascertained history has received the fullest practical exposition from Sir Joseph Fayrer,[14] but Elephantoid Fever is essentially a "medical" disease, by early management of which the physician may sometimes hope to prevent the malady from becoming developed into surgical proportions. I have already mentioned that the habitat of Indian Elephantoid Fever is in marshy places within the range of the sea-breeze, and that it is never developed up-country nor beyond the limits of the growth of the cocoa-nut tree. Dr. Pringle, cited by Waring, says that in Cochin, a place so notorious for this disease that the malady is widely known as "Cochin Leg," there is scarcely a house in which there is not one or more affected; but that in the interior, at a distance of 10 or 12 miles inland, the disease is almost unknown. In one very notorious spot, Waring found 2,133 diseased, in a population of 48,591, or 1 in 21⅔ of the whole population. Fayrer has seen elephantiasis twice only in the pure European in India, Waring neither saw nor heard of a European case. I heard of a European in Bengal, and had under my care a young man, born of European parents in India, but who had never left that country. Dr. Waring believes that brackish water is a cause of elephantiasis. The disease is common in the Delta of Bengal to a distance of at least 140 miles above the sea; but there the sea breeze prevails. There is a salt lake close to Calcutta. In the freshes, the water of the Hooghly is brackish for some miles above that city, and the water of every well in the Delta is also brackish. Webb says that it has been seen in the child which could have had no other food than its mother's milk. Waring states that quadrupeds and birds are said to be occasionally attacked in Barbadoes and other places where elephantiasis is very prevalent. In Travancore he could hear of no cases in quadrupeds; but at Allippee, a hen was brought to him in which

[14] "Elephantiasis of the Leg—of the Scrotum."—*Clin. and Path. Obs. in India*, pp. 396-409. "Filaria Sanguinis Hominis."—*Tropical Diseases*, p. 275. "Elephantiasis Arabum."—*Ibid.*, p. 258, and "Croonian Lectures, Lecture Second," 1882. The most valuable of the earlier contributions to this subject are by H. H. Goodeve; *Beng. Med. and Phys. Transactions of Beng.* vol. vii., part 1, p. 9, and Wise, *Ibid.* p. 156; Allan Webb, *Ind. An. M. S.*, vol. ii., p. 619, and an admirable report upon "Elephantiasis, as it exists in Travancore," by Dr. Edward John Waring.—*Ibid.* vol. v. p. 1. "Elephantiasis Arabum, or Cochin Leg," by Dr. Francis Day.—*Madras Quart. Jour. of Med. Sc.*, vol. i., p. 37.

one leg was very much enlarged; whether this really was the disease appeared doubtful; but it certainly bore a strong resemblance to it.

The gravest results of Elephantoid Fever, enormous integumentary growths, frequently attended with oozing varix of the lymphatics of the parts, vary greatly in different paludal localities. In and around Calcutta scrotal tumours and elephant-leg abound, and the labia and nymphæ of the female are sometimes attacked. I have seen cases of elephantoid enlargement of the integument of the forearm from the direction of Orissa. The hands are often affected in Travancore. At Chittagong, general as the paludal influence was, I never saw the scrotum attacked, but the prepuce alone was liable to suffer. I removed the growth in two of these cases. In one the mass, when dissected off, weighed two pounds.[15] This form of disease is occasionally seen near Calcutta. So rare is scrotal tumour in Travancore that Waring found it in only three cases out of 945. In Bombay the scrotum is often affected where the prepuce escapes. It appears that, there, the leg is seldom affected.

When the leg is affected, inflammation in rare cases proceeds to sloughing of the whole of the affected integument, leaving the muscles bare.[16] In a case, probably of elephantisis, by Dr. A. Garden, all the structures of the leg mortified.

The history, in all cases, is that the patient suffers from periodical attacks of intermittent, attended with great pain and swelling of the affected part. When the fever subsides the local swelling is diminished and the pain abates; but, after each successive attack, the tumour gains some accession of bulk, until, in course of years, the scrotum, for example, may attain a weight of a hundred and fifty pounds and upwards.

Waring describes the Elephantoid Fever of Travancore as characterised by a cold, hot, and sweating stage, constituting together a true paroxysmal fever, except that, generally speaking the paroxysms are more prolonged and severe in their character, mostly extending over a period of three days, and sometimes longer. There is in most cases most distressing tensive headache, lasting throughout the cold and hot stages. The cold is the most marked and severe stage. It lasts one or even two whole days, and all patients speak of it as the most painful and dreadful part of the disease. The hot stage appears also in most cases to be very severe. The sweating stage is not always present and is generally very mild; the perspiration is described as literally streaming from all parts of the body. Dr. Francis Day had a patient who died from exhaustion occurring at the termination of a paroxysm of Elephantoid Fever.

Out of 226 cases specially examined, Dr. Waring found a previous history of fever in 221, or 99·11 per cent. In the two cases it is probable that malarial influence was at work. Waring shows that when fever ceases, there is no further enlargement of the hypertrophied part.

All authorities have noticed the fact that, like my attacks of Chittagong Fever, Elephantoid Fever frequently recurs every month. The natives believe that it is influenced by changes of the moon. Both Goodeve and Wise appear to consider that lunar influence is thus operative. Webb calls this fever "Moon Fever."

Writing lately,[17] Dr. S. C. Chatterjee says, "with every approach of the full and new moon there is generally an exacerbation of fever with intensification of the accompanying symptoms showing increase of the morbid growth.

Dr. Waring has given a remarkable analysis of 224 cases, in which he was informed that the febrile paroxysm occurred — once monthly in 38; twice monthly in 37; three times in 17; four times in 6; five times in 5; once in 2 months in 10; once in 3 months in 24; once in 4 months in 10; once in 5 months, 3; once in 6 months, 9; once in 7 months, 2; once in 12 months, 8; once in 24 months, 1; irregular in 43; had only one attack, 4; no fever for one year, 2; for two years, 2; for three years, 1; for ten years, 1; for fifteen years, 2. Dr. Waring adds that, however diversified may be the interval between the attacks, yet, in the majority of instances the febrile paroxysm is stated to recur in the same individual with great regularity. A few observations in cases where the attacks are monthly, with a view to ascertain whether they have, in reality, any coincidence with the changes of the moon would either dispel a popular error or establish a remarkable law of periodicity.[18]

It does not appear that great splenic or hepatic enlargement has been noticed in any case of elephantiasis. But Webb says that, in the fatal cases which he has examined, "disease of blood-making organs, as the spleen, &c., has always been found." He also observed that "disordered excretions, particularly that from the kidney, occur during rapid progress of the disease."

Reports of careful microscopical examinations of the diseased structures have been cited by Webb and Fayrer. "They show," to use the words of the latter authority, "that though there is a great disturbance in the proportions of the histological elements, there is, after all, nothing really new." There is, in fact, "simple hypertrophy of the elements progressing most rapidly and conspicuously in parts, like the scrotum, labia, or certain portions of the integument where lymphatics most abound."

The existence of filariæ in the blood of these patients both in the nævoid or lymphatic and simple forms of the disease, has been proved by many observers; but, as these nematodes are not only present in persons apparently in perfect health, but also in association with many other forms of disease, it cannot yet be said, with certainty, that the parasite has any special relation to this malady; still, our well ascertained facts are bringing us to the verge of such a conclusion. Thus Lewis, Fayrer, Manson, Vandyke Carter, and others afford us the following data:—Chyluria, more properly lymphuria, is a lymphatic disease, so is elephantiasis. In both there is an exudation of lymph, the loss of which "exhausts the patient, just as the loss of so much blood would exhaust him." In lymphuria, the presence of filariæ is constant. Vandyke Carter has seen filariæ in elephantiasis. The increment of this latter disease is periodic. Sonsino and others observe that filarious lymphuria or hæmato-lymphuria is intermittent, with long intervals of apparently complete recovery. It now remains to be shown whether parasites *always* attend elephantiasis. Fayrer, having clearly set forth these data, judiciously deprecates hasty generalization upon them. More information regarding the association of filaria and elephantiasis is needful, and may be expected from India, especially

[15] Webb considered that when the disease attacks the prepuce or nymphæ, it is due to syphilis. See case of enormous preputial elephantiasis, 14 inches long and 12 in circumference, in a negro æt. 25, born in Africa, and sent to England from the West Indies. —*Webb. Diseases of Prepuce and Scrotum, Plate viii.*

[16] Day.

[17] *Ind. Med. Gaz.* June 1, 1880.

[18] A review of the early literature of this important question will be found at p. 113 of Dr. Henry Goodeve's sketch of the "Progress of European Medicine in the East"—*Cal. Med. and Phys. Trans.*, vol. 8, part 2—a memoir of the greatest interest and value to Indian physicians. Dr. Balfour wrote much on the effects of sol-lunar influence in fevers. His first paper appeared in 1789. A very interesting series of "Cases Illustrative of the Influence of Lunar Agency in Various Chronic Diseases," was published in 1839, by Mr. B. J. Murray—*Ind. Jour. of Med. and P. Soc.*, vol. iv, p. 570. See also p. 24 of the same volume, for a very careful review of the question "On Lunar Influence in Malarious Fevers," by Dr. W. J. Moore—*Ind. Med. Gaz.* for June and July, 1869.

upon (1) Manson's remark, that the geographical distribution of elephantiasis is much the same as that of the mosquito; and upon (2) Sonsino's conclusion that, although apparently the intermediate host of filaria, the mosquito probably plays with these parasites a part similar to that of birds with respect to vegetable seeds. Again, (3) upon the suggestion raised by that authority,[19] do lymphangitis, and adenitis, and lymphatic dilatations and rupture, with extravasation and lymphorrhagia (as in lymphuria and lymph scrotum), depend upon obstruction of lymphatic channels? Also, (4) upon the question, is lymphuria of *frequent* occurrence in elephantiasis?

Few of my readers can have failed to study with great interest Dr. Manson's most able explanation of the highly probable train of events, by which he argues that elephantoid disease is caused by embolism of lympathic glands by ova prematurely expelled by filariæ.[20] Dr. Manson shows that the parent filaria is normally viviparous, but that, like other animals, it is liable to miscarry, and the immature ovum which, rolled up, enclosed in its chorion, is of much larger diameter than the long sinuous body of the matured embryo, becomes an embolus. He gives two cases—1, of lymphatic œdema of the legs; and, 2, of lymph scrotum—in which ova of filaria were found in the lymphatics. This is, he believes, the true pathology of the elephantoid diseases: "1st, parent filaria in a distal lymphatic; 2nd, premature expulsion of ova; 3rd, embolism of lymphatic glands by ova; 4th, stasis of lymph; 5th, regurgitation of lymph, and partial compensation by anastomosis; 6th, renewed or continued premature expulsion of ova; 7th, further embolism of glands." This process, he adds, "according to the part of the lymphatic system it occurs in, the frequency of its recurrence and its completeness, explains every variety of elephantoid disease." Mr. Jonathan Hutchinson has argued[21] that between the permanent solid œdema with hypertrophy of the skin, which finally results from recurring erysipelas and true elephantiasis; the differences are only those of degree. He holds that from such cases of erysipelas to true elephantiasis it is but a few steps, and he avows his conviction, "that we shall make a definite simplification in our nosology when we class the latter disease as in the main a result of chronic and recurring erysipelas," which he regards as being "simply a specialised form of inflammatory action, and not, as it is commonly defined, a specific fever." It appears to me that the recent practical observations, made in China and India, which I have cited above, place erysipelatous œdematous thickening, and all other hypertrophic conditions of the integument, however closely they may simulate true elephantiasis, in progress and in mere external aspect, quite apart, in pathology, from this latter disease, unless it can be shown, as Mr. Hutchinson does not appear to think of showing, that recurring erysipelas, leading to hypertrophy, is caused by filariæ.

The St. John Ambulance Association.

A meeting was held at Erith, last Saturday, when certificates were presented to the police, and other classes, by Mrs. Clarkson Maynard, Sir Edward Perrott, Bart., representing the Order of St. John. An interesting incident in the proceedings was the presentation to the lecturer, Dr. Maynard, of a very handsome drawing-room clock, subscribed for by his pupils, as a mark of their appreciation of his courteous kindness and unsparing efforts to promote the success of the classes.

AMENORRHŒA AND VICARIOUS MENSTRUATION.

By SAMUEL WILKS, M.D., F.R.S.,
Senior Physician to Guy's Hospital.

I have been much impressed with the practical importance of the lecture published in this Journal by Dr. Matthews Duncan, on "Amenorrhœa and Vicarious Menstruation," for although the views therein contained are no doubt in accordance with the opinions of many experienced men, I cannot but think that a large number in the profession require to be roused up to their truth. As regards vicarious menstruation, I have never published my opinions on the subject, but as a teacher of students, I have always denounced the absurdity, as well as the error in fact, of a belief in this imaginary disorder. I have had considerable experience of diseases, both in public and private practice, and I am still waiting to see an instance of this curious condition before I can throw off my incredulity. It seems to me that some of the greatest advances in medicine have been not so much by adding new facts to our knowledge, as by getting rid of old wives' fables, which, originating in the dark ages, have finally undergone a kind of glorification in the medical mind.

If there be no such thing as vicarious menstruation, the subject had better be eradicated from our medical books, and be no longer instilled into the minds of the young, as is now, unfortunately, the case, as I know from long experience as an examiner. Such questions as the causes of hæmoptysis and hæmatemesis are amongst the commonest put to candidates for diplomas, and one never fails to hear much about vicarious menstruation. I have seen my late colleague, Dr. Peacock, at the College of Surgeons—a man of the mildest temper—get really angry when student after student would give vicarious menstruation as the first cause for hæmatemesis, looking over such frequent conditions as ulcers or cirrhosis. The reason was clear: their memory was impressed by the very strangeness and oddity of the disorder, and so it came first to the front.

But lately having had to correspond about a case of hæmatemesis, in which vicarious menstruation was suggested as a cause, I was referred, in consequence of my scepticism, to Watson's lectures, a gospel which could not be gainsayed. I gladly refreshed my memory, but was certainly surprised to find that the author regards this condition as a very common occurrence. It is remarkable, however, that he relates no case of his own, but is content to give particulars of two cases, which date back nearly a century from the present time. Sir T. Watson says, "Women are liable to perverted menstruation (so to call it) through other channels than the natural one. Hæmorrhage from the stomach occuring vicariously of menstruation is abundantly common. I told you, in a former lecture, that patients will sometimes menstruate, for years together, through the lungs, more commonly do they menstruate through the stomach." It is very significant that Sir Thomas mentions no case coming within his own knowledge, but is content to relate a case which was told him by Dr. Latham, and ends the story by saying, "This was the woman's own account, and there appeared no reason to question its accuracy." His other case is quoted from Pinel, and is that of a woman who spent her life in the *Salpêtrière:* "This woman continued to *menstruate through her lungs*, at each monthly period, from her 16th to her 58th year, *i.e.*, during 42 years." It may be observed how the change of locality of the function

lengthened its activity to a very advanced period of life.

I feel great reluctance in thus criticising so esteemed a writer as the late Sir T. Watson, but the greater the weight of his authority, the more need there is of thoroughly sifting the truth of doctrines of so extraordinary a nature as I have quoted.

As regards the other subject of Dr. Duncan's lecture, amenorrhœa, I will only say a few words, since it is treated as a substantive complaint by many gynæcologists. For my own part, I know nothing of such a disorder, nor of such remedies as emmenagogues. I believe myself that amenorrhœa, like many other complaints, is the remnant of a popular delusion, and if so, it should be eradicated, like the other disorder, from the medical mind. I have a letter in my desk, written by a qualified medical man, in reference to a young lady, the subject of phthisis, in which he says, that if I could give an emmenagogue to bring on the menstrual function, he had no doubt the patient would get better of the chest disease. I wrote back to say that I heartily agreed with him. This is only an extreme example of what one hears daily in cases of chlorosis and other disorders of girls. Feeling, therefore, so much in accord with the sensible opinions propounded by Dr. Matthews Duncan, I trust they will find their due weight on the minds of the younger members of the profession.

REPORTS OF
HOSPITAL PRACTICE IN MEDICINE AND SURGERY.

NORTH-EASTERN HOSPITAL FOR CHILDREN.

Cases under the care of Mr. GODLEE.

The following are short notes of a few cases which have occurred recently in the out-patient practice of this hospital. They are none of them unique, or indeed very rare, but taken together form a somewhat interesting group, as illustrating the manner in which different morbid conditions may be handed down from parents to offspring, or may at least occur in more than one member of the same family.

Fractures of Bones.

The father of the family, the history of which is to follow, is a healthy man between 30 and 40 years of age, who has never broken any bone; he has a brother who twice broke his arm, both times in fighting.

The mother died quite recently of an abdominal tumour, the nature of which could not be ascertained from the death certificate, which was seen by me. She had been a healthy woman previously, but once broke her arm by falling down stairs. She had two miscarriages after the birth of her second child.

There does not appear to be any other member of the family who is specially liable to fracture, except the children.

Eldest son, W., was twelve years old when he came under observation. He was one of twins, the other having been born dead. He had been under treatment for rickets and bronchitis till he was two years old, since which time he is said to have been healthy. When nine months old, he fell from a high chair, and broke his left femur about the middle, and it is said he dislocated the hip as well; the bones united in seven weeks. At thirteen months, he fell while standing by a chair, and fractured both bones of the left forearm, dislocating the radius backwards. The dislocation remains unreduced, but has left a useful joint; the fractures united in five weeks. Some time later, he broke his left forearm again near the wrist. When eleven years and four months, he struck his right forearm against his brother's elbow, and fractured it about the middle; good union occurred in five weeks. When eleven years and eleven months, he broke his left fibula three inches above the malleolus. The account he gave of the accident was, that a week before he had struck his leg against a door-post, it was swollen and sore for three days, but then recovered; three days later, however, his younger brother kicked him while asleep, or is supposed to have done so; at all events it is certain that the bone was fractured when he came to the hospital; good union occurred.

T., æt. ten, a boy, when four years old, rolled down two flights of stairs, and later on, fell from a height of ten to twelve feet, on to some stones without sustaining any injury.

A., æt. five years nine months, said to be a healthy boy. Thought to have had rickets when young. When three months old, fell off his chair and broke his clavicle. At one year and nine months, he rolled off the bed and broke his left femur; union occurred in five weeks.

E., æt. three years, seems to be a healthy girl, but her fontanella is not closed, so it may perhaps be assumed that she is ricketty. At fourteen months, she slipped off her mother's lap, and broke her left forearm above the wrist. A little later on, being lifted into bed, she struck her foot against it, and sustained some obscure injury.

A., a boy, æt. thirteen months, is a sickly child, but has sustained no fractures.

This is certainly a ricketty family; but the question will suggest itself, whether the tendency to fractures, which is undoubtedly greater than is often met with amongst ricketty children, has not been inherited, with other peculiarities, from the parents; and also whether, supposing the mother's tumour to have been malignant, this may be an example of brittle bones occurring in a family who suffer from a cancerous taint.

Hereditary White Patch of Hair.

A female child, æt. six, who was brought to the hospital for ringworm, was noticed to have a patch just above the middle of the forehead, where the skin was white; and the lock of hair growing from it was almost, if not quite, white. The mother had a precisely similar condition, and said that the lock had, at one time, been as long as the rest of her hair, but she had now cut it short. She also said that it was hereditary in her family, having occurred in two of her sisters and one brother, in her father and her grandfather, and that one of her sisters had four children similarly affected, all girls.

Talipes.

A child, seven weeks old, was brought, suffering from talipes equino-varus on one side. It had a very small fontanella; held its head back, and had a slight deformity of both ring-fingers, which were turned back at the second joints. It was the youngest of six children; the eldest also suffered from club-foot. The father had one brother and one sister; the former has eight children, one of whom, a girl, has talipes; the latter has ten children, one of whom, also a girl, has talipes.

Spina Bifida.

A boy, aged six days, had a spina bifida of moderate size in the lumbo-sacral region, the surface of which was covered with granulations and ultimately cicatrised with contraction of the tumour; both legs were contracted, and almost completely paralysed, and there was no power over the rectum or bladder. It afterwards grew fat and strong, but has developed well-marked hydrocephalus.

The mother has eight children, another of whom had spina bifida, but died when eleven days old.

Hæmorrhagic diathesis.

This is only another example of the well-known tendency of the peculiar affection to be transmitted through female members of the family to their male children.

M. L., æt. one year and ten months, presented all the characteristics of the hæmorrhagic diathesis; it was bleeding at the time from its tongue, which it had bitten; and there was the usual difficulty in arresting it. The grandfather had bled, and there was a vague history of the same thing in some great-uncle, but no trustworthy evidence could be obtained. The grandfather had two daughters only; the eldest daughter has two children, a boy and a girl; the boy bleeds. The mother has had six children, four of whom were girls, and of these two are dead, one from "consumption of the bowels," and the other from "malnutrition;" of the two boys, the elder does not bleed, and the younger is the present patient.

It is unnecessary to add further comment on these cases, which, as far as they go, speak for themselves, as illustrating what Mr. Hutchinson has recently brought distinctly before the profession under the name of the "pedigree of disease."

Medical Times and Gazette.

SATURDAY, FEBRUARY 9, 1884.

The Speech from the Throne, delivered on the opening of Parliament, on Tuesday last, referred to several measures of great weight and importance which are to be presented during the present Session. A Bill for the enlargement of the Parliamentary Franchise throughout the kingdom is to be brought in as soon as possible; the extension and reform of Local Government is to be one of the subjects of ligislation, and a Bill is to be presented for the extension of the Municipal Government to the whole metropolis; and measures relating to the security of Life and Property at Sea, to the Railway Commission and its powers, and to other subjects sure to elicit great differences of opinion, and to excite great opposition were mentioned. But the Speech contained no mention of any measure directly affecting the medical profession; nor was any reference made in it directly to sanitary matters, but it did state that the extension and reform of Local Government will include the regulation of traffic in intoxicating liquors, and Government will introduce a measure for the closing of public-houses on Sunday, in Ireland.

In the House of Commons notice was given by Members of the Government of other Bills also on disputed questions besides those named in the Queen's Speech; as for instance, a Bill to be introduced by the Attorney-General for enabling accused persons in criminal cases to give evidence. All these measures will leave Her Majesty's Government very little time, and unless they are very watchful less opportunity for effectually dealing with the Medical Acts Amendment Bill, which is, however, to be introduced at an early date. Private members also press eagerly forward to supply their co-legislators with great plenty of work. The Chairman of the Metropolitan Board of Works proposes to bring in a Bill to confer further powers on that Board in relation to the supply of water to the metropolis. Mr. A. J. Balfour intends to call the attention of the House to the condition of dwellings in crowded parts of large towns, and to move a resolution on the subject; Mr. Cohen asks for leave to bring in a Bill to secure compensation to occupiers and tenants of houses in certain cases where dwellings are taken or demolished under statuary or compulsory powers; Mr. Monckton for a Bill for the sanitary inspection of dwelling-houses; and the hon. member for Lambeth purposes to call attention to the subject of Common Lodging House Acts, and of the houses occupied by several families of the working classes. Dr. Cameron has brought in a measure to provide for the regulation of cremation and other modes of disposing of the dead; and Mr. H. Richard desires to bring in a Bill to amend the laws relating to cemeteries. Mr. Story Maskelyne will move for a select committee to enquire into the operation of the Acts for the Preservation of the River Thames. Mr. Stevenson, Mr. McLagan, Mr. Vivian, Mr. Coleridge-Kennard, Mr. C. Wilson, and Mr. T. Fry will bring forward measures for dealing with the sale of intoxicating liquors. Some old measures will also be again brought forward—Mr. P. A. Taylor, notwithstanding the crushing defeat his pet measure met with last year, will once more move the repeal of the compulsory clauses of the Vaccination Act; Mr. Anderson and Mr. Labouchere, wish to amend the Cruelty to Animals Act; and Mr. Broadhurst takes under his care a Bill to amend the law relating to marriage with a deceased wife's sister; and Mr. Warton desires to introduce a Bill to restrict the sale of patent medicine, and to call attention to the sale of certain patent medicines containing poisons; both of which subjects certainly hardly demand reform.

It is stated that the Government has decided to support the Bill to be brought in by Mr. P. A. Taylor, M.P., and backed by Sir Joseph Pease, M.P., and Mr. J. R. Hollond, M.P., for the repeal of the compulsory clause of the Vaccination Act. If passed, the Bill will initiate a very hazardous experiment. There are, we know, even in our profession, thoughtful and experienced men who hold that vaccination could be as efficiently, if not more efficiently, carried out if left entirely voluntary. The mere fact of its being compulsory, they say, sets people against it who would otherwise willingly submit to it. Martyr-making never helps a cause, we are told. We fear that nothing will convert either side, but the failure or success of the experiment which Mr. Gladstone seems bent on making. Every one would witness, with pleasure, its success; but the Government ought fully to realise what failure would mean before they throw over compulsion. Are they prepared to see the annual deaths from small-pox run up by a few thousand for the sake of a crotchet?

Mr. Brudenell Carter gave the last of his Lettsomian Lectures on Cataract, at the Medical Society, on Monday last. He reviewed the accidents incidental to early operation, the risks of the preliminary iridectomy,

and of the ultimate extraction. It was pleasant to hear that one of the results of modern improvements in the methods of operation, was to place the young beginner and the expert more nearly upon a level than was formerly the case, and that Beer's maxim to the effect "that every beginner would destroy a hatful of eyes before he cured one," was yearly becoming less and less true. The risks, advantages, and disadvantages of anæsthetics were next touched upon; the orator expressing himself in favour of what he pithily called the A.C.E. mixture (alcohol, chloroform, and ether), and what Billroth calls the 1, 2, 3 mixture, to denote the proportions in which the compound should be made. The complications which may arise after operation, and their treatment, brought the lecture to a close.

Mr. Brudenell Carter himself tersely summarised the three lectures as follows:—They showed that the performance of iridectomy as a preliminary operation, and the subsequent employment of a comparatively small section through the tunics of the eye, have combined to render the extraction of cataract a more simple, and hence a more frequently successful, operation than it has been at any previous period, and that these improved methods now enable surgeons to deal with the disease at a comparatively early period of its history.

At the meeting of the Pathological Society's Meeting, last Tuesday, sporadic cretinism formed the first and chief part of the evening's entertainment. Mr. Bowlby shewed how the long bones became stunted by the ingrowth of connective tissue at the growing end, from the deep layers of the periosteum, and Dr. Barlow added another plea in support of the absolute non-identity of this disorder and rickets. He also demonstrated that absence of the thyroid gland is not a *sine quâ non* in sporadic cretinism. It is, indeed, very seldom that two such good papers on the same subject are read at the same meeting of this Society.

Dr. Hale White exhibited a section and drawing from a case of fibroid disease of the heart, in which death had taken place suddenly, without previous symptoms, and Mr. Benton communicated a case of hard carcinoma of the œsophagus. Sir Henry Thompson brought forward a villous tumour of the bladder, which he had lately removed, and also shewed four specimens of sacculated calculus. The narration of this latter group, led to a smart little passage at arms between Sir Henry and Mr. Thomas Smith, and Mr. Black, as to the differential diagnosis between a sacculated calculus and a calculus impacted in the ureter but prolapsed into the bladder.

The annual meeting of the Obstetrical Society was held on Wednesday evening. Dr. Matthews Duncan exhibited Auvard's "couveuse," or "nest," as Dr. Duncan preferred to call it, for the rearing of premature children, a contrivance which is stated to have reduced the mortality among such by nearly one-half. Dr. Godson exhibited Hearson's "incubator," which was described to the Society by the inventor. This, intended for the same purpose, is said to be automatic in action, but is more costly, and less simple. Some specimens were exhibited, notably a uterus, removed, with success by the vaginal method, by Dr. W. A. Duncan. The rest of the evening was taken up with the business of the annual meeting, and the President's address.

A communication will be made by the President at the meeting of the Royal Medical and Chirurgical Society on Tuesday next, from Dr. Straus of Paris, chief of the French Scientific Commission, sent to Egypt to investigate the cholera. Dr. Straus's microscopical specimens will be on view half-an-hour before the meeting, and Prof. Marshall's communication will be made at about 9.30, after the discussion of Dr. Broadbent's paper.

Sir Joseph Lister was entertained at dinner by the Manchester-Edinburgh University Club, at the Queen's Hotel, in that city, on the 31st ult., and the men of the North, showed, by the warmth of the welcome which they accorded to him, their high appreciation of his personal character, and of the value of his services to the science and art of surgery. In responding to the toast of his health, which was proposed by Dr. Thorburn, Sir Joseph Lister said that it was with great hesitation he had accepted the honour recently conferred on him, an honour which he had never coveted. When, however, the Prime Minister, on behalf of Her Majesty, offered him a baronetcy, in recognition of "the distinguished services rendered to his profession, and to those interests of suffering humanity with which it is inseparably connected," he felt, on reflection, that he could not decline what was really a tribute to those principles which he had so long striven to maintain. Remembering, however, that some of the grandest heroes in the history of British surgery—men in the presence of whom he felt like a dwarf amongst giants, men like Cheselden, Hunter, Abernethy, and Syme—had gone to their graves with no other recognition than the imperishable renown that attached to their achievements, he would almost have been pleased to remain untitled.

The graceful and unaffected modesty which gave a charm to Sir Joseph Lister's speech at Manchester, has been characteristic of him throughout his career; and has, it may be argued, been instrumental, in no small degree, in securing the widespread acceptance of his principles and practice during his own life-time, and their titular acknowledgement, while he is still in the prime of his days. Had his views been advocated with acerbity and great personal assertion, they would have aroused an antagonism which would have delayed their general adoption, and he might have sunk into his grave, like the great surgeons he named, without any social distinction. But while steadfastly maintaining his position, and neglecting no line of argument that could advance his principles, Sir Joseph Lister has never condescended to clap-trap, and has been studiously considerate to his opponents, and has thus pursued the long campaign in which he has been

engaged, unembarrassed by those personal skirmishes, and outpost irritations which waste time and retard progress.

A CHARACTERISTIC instance of his modesty and aversion to noteriety, has come to our knowledge lately. When the Empress of Germany passed through London some years ago, she sent for Sir Joseph, then Mr. Lister, to Claridge's hotel, where she was staying, and formally thanked him for the benefit which his discoveries had conferred on the Fatherland. Listerism, she said, had, to her knowledge, saved thousands of lives and limbs in Germany, and she could not be in London without telling the author of that system how highly she valued it. It can scarcely be doubted that in the case of many surgeons, some intimation of such a singular mark of imperial favour would naturally and justifiably have found its way into the papers, but Mr. Lister omitted to mention the incident even to his friends, and it was only recently that the fact of such an interview having taken place between him and the Empress leaked out.

AN epidemic of canine chorea is reported from Liverpool, by Mr. W. J. Welsby, in the pages of a contemporary. The first pup affected was one of a litter of eight, and the chorea came on just after the distemper. The puppies were then separated, three being left with the one affected with chorea. Two days later, these three all had chorea; two of them were then removed and kept separate, and these recovered, the others, *i.e.*, the one first affected and the one left with it, died; no lesions were discovered in the brain or spinal cord, but we are not told that these were examined under the microscope. It is noteworthy that in the case described by Dr. Gowers and Dr. Sankey, in the *Medico-Chirurgical Transactions* for 1877, the affection followed the distemper.

SCIENCE and common sense have won a notable victory at Oxford. It will be remembered that in June last a sum of 10,000*l.* was voted by the University for the purpose of erecting and furnishing a laboratory for the new Professor of Physiology, Dr Burdon Sanderson, and it was thought that, the principle once admitted, the formal vote for the selling out the necessary stock would pass Convocation without difficulty. But Dr. Sanderson had declined to pledge himself to dispense with experiments on living animals in the prosecution of his researches, and the anti-vivisection party determined to import into Oxford the obstructive tactics which have met with so much success at Westminster. They declared that the vote of June had been snatched by a small majority of three, in the absence of many non-resident M.A.'s who knew nothing of the matter until they saw in the papers that it had been decided, and they sent out an urgent whip, calling on all who had agreed with them to come to Oxford and vote against the proposal. If they had been successful, the only result would have been that the authorities would have been obliged to obtain the necessary moneys in another way. As it is the obstructives have been out-voted by a much larger majority than that by which the proposal was originally carried. The effect of this ill-advised attempt on the part of non-residents to dictate to those who are responsible for the University teaching has been that a carefully regulated vivisection—and that is all that Dr. Sanderson demands—has been practically sanctioned by the Oxford graduates by a majority of 188 votes to 147.

THE Cambridge Medical Graduates' Club are about to give a conversazione to their professional brethren of the sister University. Graduates of either University, who are at present studying medicine in London, will also be invited. The 29th of February having been selected as the most suitable day, the committee have decided to protect their unmarried guests by excluding ladies in favour of the fragrant weed.

THE deaths last week in London were 450 below the ten years' average, and the death-rate was 20·7 per 1,000. The deaths from zymotic disease were 59, and those from respiratory diseases 281 below the average. The past five weeks, during which the death-rate has averaged 20·4, or nearly ten per 1,000 lower than it was in the corresponding period of 1880, has been quite an exceptional period, so warm a January not having been known for years. The progress of sanitation is reversing the saying, that "a green Yule makes a fat churchyard," which was, no doubt, true enough when vast tracts of country were undrained, and typhoid and ague committed their ravages unchecked. In the present mild winter there have been more illnesses in the metropolis of an agueish nature, than have been known for years. A century, and still more, two centuries, ago, in such a winter London physicians would have had their hands full of them. We are apt to forget that even great personages used to die of ague.

THE most fatal zymotic disease, both in London and the other 27 great towns, still continues to be whooping-cough, which was credited last week with 85 deaths in the former, and 14 deaths in the latter. That is to say, whooping-cough killed just 50 more children in London, than it would have done if it had been no more fatal than in the other large towns. We again assert that this excessive fatality of whooping-cough is a subject which calls for attention. During the last quarter of last year, the deaths from whooping-cough in London were 380, while in the 27 other great towns, which have in the aggregate a population of about 700,000 more than London, the deaths were 385, so that it is to be hoped that this recent disparity is only a passing occurrence.

THE Registrar-General's return for the last quarter of 1883 has just appeared. The birth-rate, 31·8 per 1,000, was 2·4 below the ten years' quarterly average, and lower than in any corresponding quarter since 1855. The death-rate, 19·1 per 1,000, was also 1·8 below the ten years' average, though not so low as in the last quarter of 1881. If the death-rate had been as high as the average in the forty-five preceding corresponding quarters, seventeen thousand more persons would have disappeared from amongst us; or, in other

words, every doctor in the kingdom would on the average have had one more death to certify. In the chief towns the death-rate was 20·7; in country districts 16·6; the former being 2·2, and the latter 1·4, below the ten years' average. The metropolitan death-rate for the quarter was 20·3, and in the twenty-seven large towns, 21·9; Manchester heading the list with a rate of 27·9.

During the quarter, scarlet fever was the most fatal of the zymotic diseases. It was exceptionally prevalent in Wigan, Ashton-under-Lyne, and Dudley. Diarrhœa came next, and was again most fatal at Dudley. Measles was most fatal at South Shields, enteric fever at Preston and Wigan, and whooping-cough at Huddersfield. The death-rate from diphtheria during the quarter was higher than in any corresponding quarter during the last fourteen years, but as the Registrar-General remarks, the returns were so unsatisfactory that it is really impossible to say with certainty whether there has been a real increase in the disease, or only an increased use of the term in certificates. It was very prevalent in London and its neighbourhood, the death-rate from diphtheria in the metropolis being 0·29, and in the rest of Middlesex 0·40 per 1,000, whereas the rate for the whole country was only 0·18, and the average rate for the ten preceding last quarters only 0·14. The number of deaths from diphtheria in London during the quarter was 288, and in the other 27 great towns (with an aggregate population of 700,000 in excess of the metropolis) it was only 134. It is difficult to believe that all this difference is to be accounted for by irregular registration. But we dwellers in London may congratulate ourselves that our state as regards diphtheria prevalence compares most favourably with that of some of the continental cities. In Paris, with a population of over two millions, there were during the quarter 502 deaths from diphtheria and croup; in Amsterdam, with a population of 350,000, as many as 434 deaths, and in Berlin, with something over a million inhabitants, there were close upon a thousand deaths from the same disease.

In the short summary of the returns for 1883, appended to his quarterly report the Registrar-General states that the birth-rate in England and Wales, 33·2 per 1,000, showed a further slight decline from the steadily decreasing rates of the six preceding years, and was lower than in any year since 1849. This progressive decline in the fecundity of English women, though partly traceable to commercial depression, is a phenomenon to be noted. The death-rate for 1883, viz., 19·5 per 1,000, was, with the exception of 1881, lower than that recorded in any year since registration came into operation in 1837. The mean annual death-rate during the first three years of the present decade, 1881–1890, was 2·1 below the mean rate in the preceding ten years, 1871–1880; nearly 165,000 more people would have died in the three years if the mean rate of that decade had been kept up. The deaths from zymotic disease in 1883 numbered 58,272, and were as many as 13,216 less than the number recorded in 1882. The zymotic death-rate which had been 3·87, 4·11, and 3·36 per 1,000 respectively, in the three decades from 1850–1880, did not exceed 2·42 in the first three years of the current decade. So that, if we are not breeding so freely as in the past, we are much more successful in rearing our brood. Nothing could give sanitarians greater encouragement than to see the success of their efforts in controlling the waste of human life.

Professor Huxley's article in the current number of the *Nineteenth Century* is practically identical with the address which he delivered at the London Hospital in October, which was criticised in these pages, not altogether favourably, at the time. On some points we cordially agree with Prof. Huxley. No one is more convinced than we are as to the necessity for introducing radical changes into the arrangements for primary medical education in the metropolis. Attention was first called to the subject many years ago by Dr. Acland, and since then the competition of the Scotch and provincial schools has been slowly forcing conversion upon many of the metropolitan teachers. The smaller schools will have to amalgamate their chairs in all the primary subjects, their dissecting rooms, and physiological laboratories, if they are to contend successfully with Edinburgh, and the rising schools at Cambridge and Manchester. As Prof. Huxley says, the thing has to be done somehow or other.

Another point in which we agree with Prof. Huxley is, in thinking that the immediate passing of a Bill of a couple of clauses, enforcing a threefold qualification, and giving the Medical Council a more real control over the examinations, would be better than waiting on the pleasure of Parliament for a more complex measure. The profession is heartily sick of medical Bills, and would welcome any settlement that cut the ground from under the corporations that trade upon their licensing privileges. But the first requirement of any settlement is reform of the Medical Council. It would be absurd to trust greater power to the Council so long as members are seated upon it for the express and avowed purpose of safeguarding the vested interests of the corporations.

Professor Huxley is one of the old school of radicals, and has a horror of State intervention. He follows in the footsteps of the Bishop of Peterborough, and would, probably, sooner see a nation poisoned by quacks and chemists than limited in its freedom to get medical advice where it listeth. He thinks the State is only justified in intervening in medical affairs on the ground that it is advisable for it to have some guarantee as to the accuracy of death certificates, the value of medical evidence in courts of law, and the skill of those whom it appoints to its naval, military, and civil appointments. Prof. Huxley has a perfect right to his opinion, but as it happens the State does not accept it, nor will other people.

The State's theory of its function and its influence is both wider and narrower than that which Prof. Huxley would force upon it. The State evidently does not

think it necessary only to warn one of its subjects, as to who are qualified medical practitioners, when he has made up his mind to die, and is likely to be in want of a death-certificate. For it has passed an Act enforcing an examination on the dentist, who has nothing to do with death certificates, law courts, or the public services, and will probably ere long enforce the same on the midwife, who, it is to be hoped, will have equally little to do with them. Again, the State's theory of the efficacy of its intervention is narrower than Prof. Huxley's, for it will not accept registration on the medical register, which itself called into being, as a sufficient guarantee of competence for its own services, but imposes on candidates a further qualifying examination.

The truth is that the State has made up its mind that it is bound to take care of the general public, and assume the duty of pointing out to them whom they may safely trust. Prof. Huxley says, "The state does not profess to tell the public that one man is a qualified engineer, and that another is not so." Quite true. It does better. It sends its representatives to test his work, and will not let its subjects risk their precious lives on the smallest railway bridge till it has been officially declared safe. But the State cannot test the harmlessnes and appropriatness of each prescription, and it has, therefore, made up its mind to give a general guarantee of fitness. And this reading of its conduct is so widely admitted that the principle is more likely to be extended than to be limited. Wherever people are not in themselves competent to judge whether they are in safe hands, the State is bound to give them some protection. And it is the neglect of this duty that has covered the country with unsafe and unsightly buildings, has left secondary education to those who have failed in other walks of life, and has allowed the sewers in every town, London included, to be laid so incompetently that they are in most cases a chain of cesspools. We are not sure that much of the present outcry about the dwellings of the poor would not have been unnecessary if house-owners had been obliged to show a competent knowledge of their business.

It must be admitted that, with all his clearness of perception, Professor Huxley does not invariably take a fair and reasonable view of things. Speaking of counter practice, he incidentally remarks, "Is a man who has a sudden attack of pain in tooth or stomach, not to be permitted to go to the nearest druggist's shop and ask for something that will relieve him! The notion is preposterous." With all possible regard for the weight of Professor Huxley's opinion, it is worth pointing out that in his statement of the case he is begging the question. There is confusion of ideas in his sentence. No one would object to a sick person asking for something," as responsibility then rests on the individual, if, to put it mildly, the treatment goes wrong. But this is not the usual mode of procedure; the chemist is asked for "anything," and thus the treatment comes from one, who, as our author remarks, "has not paid sixpence for his medical training, because he has never had any." A single instance may counteract the spread of erroneous inferences from apparently plausible arguments. A man with chronic kidney disease might apply for relief of gastric pain, and have op um given him "across the counter," a possible consequence being renal convulsions, coma and death. Surely it is not "preposterous" to object to this on grounds of "public policy."

Mr. Christopher Heath has undertaken to edit for Messrs. Smith and Elder a "Dictionary of Practical Surgery," on the lines of Quain's Dictionary of Medicine, which has scored such a satisfactory success. The new dictionary is to be a compendium of the practice of surgery of the present day, readily available for reference by the busy practitioner, and it is hoped that it will be published within two years from now. The articles will be signed, and will be expressed as concisely as possible, historical details being omitted, and questions of pathology only discussed when absolutely necessary. The profession will look forward with great interest to the publication of this work, which is much wanted, and which will no doubt fully come up to the expectations which all who know its editor will have formed of it.

The French Ministry has at last summoned up courage enough to administer a rap on the knuckles to that restless and meddlesome body, the Paris Municipal Council. This body, after voting 17,607,000 frs. as its share of the expense of the Assistance Publique for 1884, added the proviso that this contribution should only be given on the conditions that in at least two of the hospital establishments all the religious associations should be replaced by lay ones before the 1st of April, and that the services of the other hospitals should be so transformed in a similar manner as rapidly as possible during 1884. In a decree of President Grévy, annulling this proviso, it is stated that the administration of the Assistance Publique is placed under the authority of the Minister of the Interior and the Prefect of the Seine; and is entrusted to a director acting under the surveillance of a council. The function of the Municipal Council is limited to giving its advice as regards the accounts and revenues of the Assistance Publique, and to expressing its wishes on questions of a purely local interest; and it cannot interfere with the internal management of the hospitals, without encroaching upon the rights of the Director of Public Assistance. The Government is about to bring in a Bill for the purpose of more exactly defining and limiting the actions of the Council.

Professor Frerichs, who, as we recently mentioned, will shortly celebrate the twenty-fifth anniversary of his connection with the Berlin University, has received from the Russian Government the Grand Cordon of the Stañislaus Order, as a reward for eminent services rendered in the education of Russian students during his lengthened period of teaching in the Universities of Breslau and Berlin.

The Berlin Polyclinic, which was founded towards the end of 1882, on the lines of the well-known institution at Vienna, has had a very successful first year,

⁂

more than two hundred medical men having joined its classes. All the special subjects are taught, and there are two laboratories connected with the institution, for the study of chemistry and histology respectively. A third laboratory, intended for the study of micro-organisms, is to be added. Each course begins on the first of each month, and instruction is given every day, Sundays and holidays excepted.

It is announced that Dr. Theodore Williams is laid up in the Riviera with typhoid fever, and that Mr. J. S. Balfour, Mayor of Croydon and M.P. for Tamworth, has been struck down by Roman fever since his return from a tour in Italy. Last summer one of England's most eminent men of science, Mr. Spottiswoode, succumbed to fever which he contracted in Rome; and, amongst persons less prominently in public view, cases of serious illness followed upon visits to the Continent in search of health or pleasure. Some so-called Health Resorts are, it is to be feared, little better than ambuscades of disease, where invalids may incur maladies more formidable than those from which they seek relief, and where those who accompany them run risks of being themselves invalided. With the decline of pedantic therapeutics, there has arisen an increasing appreciation of the beneficial effects that may be obtained in various degenerative and pre-degenerative states from change of climate, and with the increase in facilities of locomotion, there has come a remarkable increase in the flocks of English people who migrate to the South for the winter months.

It is but reasonable that our health emigrants, as well as our industrial ones, should be well informed as to what they may expect in the place to which they direct their steps, but the former are nearly as apt to be deceived as the latter, by the specious and misleading accounts given by persons who are interested in vaunting the merits and salubrity of their particular districts. The epidemic or contagious diseases must be of an exceedingly pronounced type to obtain recognition in a fashionable health resort, the leaning of every one being towards an optimistic view of the sanitary situation. So powerful is self-interest in perverting judgment, that it would well seem that the local authorities of those places where invalids do congregate should not be subjected to the temptations involved in issuing health reports on their own localities. A roving medical commission of English physicians, visiting during the autumn months the principal winter residences frequented by our countrymen and countrywomen, and issuing reports on their sanitary arrangements and conditions, would perform a most useful work, and exercise a salutary influence. In all health resorts there ought to be not merely registration of deaths but careful and complete registration of sickness.

It is assumed, at law, that every Englishman knows the laws of his native land; and, though the assumption seems a large one, certainly every one who breaks a law is liable to punishment for his misdeed, even though he may have been ignorant that he was offending. In some such cases any punishment, however slight, may seem harsh, for who, except a lawyer, can be expected to be at all fully acquainted with even "common law"? Every professional man, however, may surely be fairly expected to have a good knowledge of the laws that concern his special calling. But, from a letter recently addressed by the Commissioners in Lunacy to the Royal College of Physicians of London, and no doubt to other licensing authorities, it appears that not a few medical men either do not take the trouble to make themselves acquainted with, or most carelessly disregard, legal enactments that seriously concern their professional actions. The attention of the Commissioners had lately been called to several cases in which certificates of lunacy had been given by practitioners who were not on the Medical Register. Now, under sect. 37 of the Medical Act, 1858, no certificate required by any Act of Parliament from any medical practitioner is valid, unless the practitioner signing it, is registered under the Act; and an unregistered medical practitioner makes himself indictable for a misdemeanour if he signs any such certificate, and states therein that he is a "physician, surgeon, or apothecary," as these terms, when employed in an Act of Parliament, "mean a person registered under the Medical Act."

A certificate of lunacy signed by an unregistered practitioner is invalid; and the detention of a patient under it, is unjustifiable at law. Such errors cause expense and great inconvenience, in legalising the further detention of patients by fresh certificates, for which purpose the patients must be temporarily removed from any asylum in which they may have been placed. There can be no justification of any such faulty certificates, and we trust that no medical man will, for his own sake as well as on account of the patients, again commit such a serious error, as to give a legally invalid certificate of lunacy. The Commissioners in Lunacy suggest that it would be very desirable that a written or printed notice of the necessity of registration as a condition for giving certificates be furnished to every new member or licentiate of the Royal College of Physicians. The College will, we believe, carry the suggestion into action; and no doubt other licensing bodies will take like precautions.

The British jury has surpassed itself. A herbalist gives for a serious malady in a patient, whom he has never seen, a remedy, of the serious nature of which he is equally ignorant. The patient swallows it, and immediately dies, and the jury, before whom he was tried, acquit him, with the recommendation to be more cautious in the future in the use of "disputed" drugs. We venture to affirm that if James Wallis had been a licensed medical practitioner, and had prescribed in a similar manner for a patient he had never seen, the jury would have taken a very different view of the case, and no one probably would have criticised them. The logical deduction from their verdict, is that ignorance shooting with its eyes shut may be more safely trusted than the watchful and cautious aim of science.

The question of "educational overpressure" is exciting very widespread attention, and will no doubt be thoroughly discussed in Parliament before many weeks are over. An important meeting in which the doctors took a leading part, was held, with reference to the subject, at Bradford, on Monday. Lord Stanley, of Alderley, who was in the chair, said that "the increasing exigencies of the new Code, and the system of payment by results, converted every teacher, whether he would or no, into an overseer of slaves, bound to extract the utmost amount of labour from the unfortunate children under him. The subjects to be taught were such as to render the tyranny of lessons necessary, and such lessons were detrimental to the growth and future health of the children." Mr. Pridgin Teale proposed as a resolution, "that the system of payment by results, as at present carried out, acts injuriously upon both health and education, and that it ought to be modified, so that a great portion of the Government grant may be given for a general average of the moral, physical, and intellectual well-being of the school." Mr. Stanley Leighton, M.P., seconded the resolution, which was carried, as well as others, including one protesting against compulsory home lessons for children under ten years of age.

Meanwhile it is incumbent on the promoters of this most reasonable agitation to see that their cause is not injured by over-zeal on the part of some of their adherents, or by the production of cases of alleged evil results from over-pressure, which will not bear the jealous scrutiny of the Education Department. A case that is brought forward, and fails, probably does more harm to a cause than one that is indisputably proved helps it. The correspondence published in the *Times* of Friday last will show how carefully a case must be observed and reported if it is to convince Mr. Mundella. The Department still maintains an attitude of scepticism on the subject, and will no doubt be able to throw doubt, and on many of the cases which are likely to be brought before it. But there is, we are assured, no lack of instances in which the serious effects of educational pressure can be proved to demonstration, and it should be the aim of all to bring forward all the definite evidence they are able to collect, while steadily repressing all that will not bear scrutiny. It is to be hoped that there will not be many such lamentable cases as that of the boy who committed suicide at West Bromwich, from the alleged effects of over-work at school. Evil enough can be wrought before the suicide mark is reached.

The history of some of the cases got up by the anti-vaccinationists should warn the critics of the Education Code to beware of similar bogus complaints. One of these cases has recently been investigated at Blackburn, for the Local Government Board, by Dr. Page, who succeeded in eliciting most clearly, that the child, whose death was attributed to vaccination, had died from malnutrition, the result of bad nursing and drugging. It was perfectly free from any lumps or abscesses, and there was no discharge or peculiarity about the places of vaccination, which had been performed six weeks before the child's death, and was proved to have run its normal course. There was no idea of vaccination having anything to do with the child's illness until after its death, and the mother had nothing to say against the operation. Under these circumstances it would be difficult to understand how the charge could have been set on foot, had not Dr. Page thoroughly explained it.

This was how it happened. Mr. Gregory Walker, the undertaker who buried the child, is a member of the Blackburn Anti-vaccination Society, and a great friend of Mr. Thomas Duxbury, its secretary. He alleges that he observed that when he saw the child after death, "the pocks or vaccine marks were actually bursting," an appearance, it may be added, which was witnessed neither by the mother, nor the woman who had had charge of the child, nor indeed by anyone but the undertaker. Mr. Gregory Walker disclosed the horrible sight to his friend, Mr. Thomas Duxbury, who without delay, addressed a letter of complaint to the Blackburn Board of Guardians. The child died on December 4th, and Mr. Duxbury's letter was received on December 8th, and on the same day, an anonymous advertisement appeared in the *Blackburn Times*, headed, "Death after Vaccination," and repeating the very words used in the letter to the Board. We hope that it will be long before the agitators against educational overpressure take to founding their cases on the pathological observations of undertakers.

Hunting casualties seem to be unusually numerous and fatal during the present season. The *West Sussex Gazette* reports an unfortunate instance, in which the "first whip" of Lord Leconfield's hunt has died, as the result of an accident in the hunting field. In this case, a kick from his fallen horse caused what appeared to be an unimportant scalp wound in the temporal region. This shortly healing, the patient, contrary to the advice of his medical attendant, mounted his horse, and rode for some hours in search of a missing hound. He returned aphasic, and convulsions, coma and paralysis terminated the illness, fracture of the inner table of the skull being the case of the fatal result. This is an additional instance, if such were needed, of the advisability of guarded prognosis, and seemingly even extravagant, care in case of scalp wounds produced by sharp or heavy blows.

The *Philadelphia Medical Reporter* calls upon medical editors, members of medical societies, and practitioners in general, to protest against and resent an "insult to the profession" offered by the Red Star Line Atlantic Steamship Company, sailing under the Belgian flag, but mainly owned and officered by Americans. The insult in question consists in an order issued by the company, that in future the ship-surgeons shall mess at the second-class table, and rank in other respects only as second-class passengers, whereas in all other lines they are assigned quarters and mess with the first-class. Several of the surgeons of the company have resigned, and others are only waiting in hopes that the remonstrances which are being adopted by members of the profession

may induce the company to withdraw its decree. As the Red Star Line, as yet, does not even deign to give any reply to these, the *Reporter* calls upon every practitioner to refrain from selecting or recommending this line for travelling, which offers no special advantages over all the others which treat their surgeons with due respect. It is pleasant to notice this manifestation of sympathy, and we can only wish it success.

One of our correspondents sends us the following :—"I crave your permission to say a few words on the Home Hospitals Association for Paying Patients, to the successful working of which you made allusion last week. The success of Fitzroy House *as a surgical home* is beyond all dispute ; as one who has treated patients within its walls, I can bear testimony to its unequalled resources, and to the excellence of its internal arrangements ; the latter appearing to me to depend largely on the special qualifications for her office which distinguish the present lady superintendent. My particular object in addressing you is neither to find fault with, nor to praise, the working of Fitzroy House, but to ask whether Fitzroy House is fulfilling the purposes for which it was founded. I turn to Mr. Burdett's book on "Pay Hospitals,"[1] where, in chapter IX., the question is dealt with. Your space is valuable, or I should ask you to allow me to transcribe several pages from it. I must content myself by requesting you, Sir, and those of your readers who are interested in the matter, to study this chapter carefully over, and then say whether Fitzroy House is a success. As I understand the chapter, the home hospital was established for the poorer middle classes—young milliners, clerks of various kinds, teachers, press writers, students, and the like—for a class of persons indeed, independent but poor, whose home surroundings were prejudicial to the recovery of the health lost through over-work in overcrowded rooms, late hours, and other hardships incidental to London life, and the general struggle for existence which now so besets us."

"I ask how many of this class have been admitted and treated ? What has Fitzroy House done to mitigate the evils which Mr. Burdett so graphically describes ? What has it done in the matter of overcrowded rooms ? How many of the '40 young women engaged in a cellar beneath a shop in Tottenham-court-road, which was lighted by gas, and where the air space allowed to each person was but 50 cubic feet' (*op. cit.* p. 105), or their successors have been treated in the *Home ?* Or let me ask what has the Association done for the class of persons represented by 'the old public school and university man with an income of 200*l.* derived from his profession.' (*Op. cit.* p. 112.) The smallest charge at Fitzroy House is 3*l.* 3*s.* per week, and I believe I am right in saying there are only two rooms for which this minimum charge is made. The association would do well to publish the rank or occupation of every person treated in their wards, together with the fee paid to the attendant surgeon. The public would then be able to judge for themselves how far the professed objects of the association are carried out in practice. If the convalescent home is to be worked on the same system, it will be honest, even if not judicious, to say so. I do not gather from your remarks, whether convalescents from infectious diseases are to be housed in the same institution as those who are recovering from non-infectious disease."

The first part of an epoch-making undertaking—the historical English Dictionary, edited by Dr. James A. H. Murray—has just been issued from the Clarendon Press ; the editor has been assisted by Dr. Pye-Smith, in his treatment of medical and biological terms ; by Dr. Watts and Professor Roscoe, in reference to chemical words; while he has also received assistance from Mr. Henry Power, who, as joint editor of the Sydenham Society's Lexicon, may be considered to be one of our best authorities on medical terminology.

Armand Leslie, who, sword in hand, was cut down by the Arabs in the massacre of Baker Pacha's troops, on Monday, was well-known as a red-cross surgeon. He was principal medical officer of the National Aid Societies' Ambulance in the Russo-Turkish war, and received the Osmanie and Medjidie Orders for his services ; and he did such good service in the recent epidemic of cholera in Egypt, that a permanent post was offered him by the Egyptian Government and accepted. Leslie was a Middlesex Hospital man, but had also studied in Paris. He took his diploma in 1868. He was one of those adventurous spirits who fret under the routine of common practice, and love nothing better than to be in the midst of danger and excitement—a modern red-cross knight.

Under the auspices of the American Association of the Red Cross, the first number of the International Review of Medical and Surgical Technics has lately made its appearance. It is a periodical devoted chiefly to the description, illustration and discussion of instruments, appliances and methods of operations that have been recently devised or published. It will also take into consideration the manufacture, use, care and repair of instruments and new methods for prepairing and administering drugs. The reason for its appearance is that "the busy practitioner has neither the time nor the opportunity to read, much less to digest, the vast amount of periodical literature pouring in upon him !" The present number contains a great deal of information, both useful and interesting, and is well got up in all respects.

DR. HUNTER'S REPORTS ON THE CHOLERA EPIDEMIC IN EGYPT.

In our last week's issue we mentioned that Surgeon-General Hunter's cholera report, or rather reports, for there are two, had just come into our hands. The first is dated Cairo, August 19, 1883; and the second, London, December 11, 1883. These reports, with appendices, cover 71 pages, and form the last of three volumes issued simultaneously by the Foreign Office. The first two of the series consist of the

1 "Pay Hospitals and Paying Wards throughout the World." By H. C. Burdett. J. and A. Churchill. 1879.

correspondence which has taken place respecting the origin and progress of the epidemic, and concerning matters more or less directly related to it. The information embodied in these two volumes, formed the basis for the report of the English delegate to Egypt, and, after a careful perusal of them, we cannot refrain from congratulating Dr. Hunter on having been able to reduce such a chaotic mass of facts and fancies into something like order, within so short a time. In reading the correspondence, one is struck with the circumstance that nearly every writer—whether professional or lay—has formed certain notions of his own as to the ætiology of the disease, but the communication which seemed to us to be the most striking and instructive in the two first volumes of the series, is one by Drs. Chaffey Bey and Salvatore Ferrari. And what specially induces us to single out this correspondence, is the circumstance that the facts elicited by the reporters in the course of their enquiry as to the origin of the outbreak at Damietta compelled them to write, and that with considerable ability and force, in direct opposition to their own preconceived ideas on the subject.

They write : "Was the cholera, which appeared on the 22nd June, 1883, at Damietta, imported thither from some country where it already existed in an endemic or epidemic form? We recently watched three consecutive outbreaks of epidemic cholera at Mecca—those namely of 1878, 1881, 1882—and showed well-nigh material proof that the malady was each time imported into Hedjaz; we were, therefore, till now great partisans of the theory of importation, and would not have hesitated for a moment to have pronounced in favour of importation in the present case also, had the facts, which we searched for most carefully in order to arrive at this conclusion, appeared in any way reliable." The theory which was stated by Dr. Flood, a Norwegian, and which is still maintained in some quarters, that the disease was brought to Damietta from Port Said on the 18th of June by a native stoker of the steamer *Timor* from Bombay, was thoroughly enquired into by these gentlemen, and shown to be wholly untenable; and it now appears that the man had left Port Said on the 18th of the Mohammedan month *Shabân*, which Dr. Flood had mistaken for 18th of June. Now, Shabân 18th corresponds to June 23rd, and the stoker was proved to have arrived at Damietta on the 24th June, or two days after several well-recognised *deaths* from cholera had been recorded at that place. After having thus disposed of this and of several other theories as to the probable origin of the disease, Drs. Chaffey Bey and Ferrari write : "Seeing these facts, we now find it positively impossible to pronounce in favour of the importation of the cholera of this year into Damietta."

This is likewise the conslusion which Dr. Hunter has arrived at, not only as regards Damietta, but also as regards Egypt generally. It is very evident that it has only been with the greatest difficulty that he has succeeded in collecting even general information regarding the history of cholera in the country, and as to statistical data their extent and value may be inferred from the following remarks :—"It is quite rare and exceptional for persons suffering from disease to be seen during life by a medical man. The village barber is the registrar, and according to the statements made to him by the relatives or friends of the deceased, he enters on the register what he considers to be the cause of death, and then grants a permit for burial. It is, however, abundantly evident that Dr. Hunter has succeeded in unearthing facts which prove that cases of undoubted cholera have been observed in Egypt every year during the last twenty years or more." Dr. Hunter, further, "feels little doubt that examples of cholera are not of infrequent occurrence in many of the cities and towns of Europe, not excluding the British Isles. In certain parts of the Russian Empire cholera is affirmed to be endemic." These remarks call to mind observations which were made a few years ago by Lewis and Cunningham in their report on *Cholera in Relation to Certain Physical Phenomena*, excerpts from which appeared in the *Practitioner* for April and May, 1878. Referring to certain isolated cases of the disease as having occurred within their own knowledge, they write : "Somewhat similar cases habitually occur in every city in India, as well as every summer in all the larger cities of Europe. These, however, excite no special comment, unless an epidemic breaks out in any part of the country; on this the previously ignored cases are carefully collated and described as the starting-points of the disease; it is not the custom to look upon such cases *then* as due to a localised generation of the disease."

Dr. Hunter reviews at some length the evidence which has been adduced in favour of the germ theory of the causation of cholera, and, after pointing out that the negative results obtained in this direction by the French Mission to Egypt were wholly confirmatory of those arrived at in India by Lewis and Cunningham, he expresses his belief, as we mentioned last week, that Koch's cholera-bacilli are the result of decomposition. The question of the causal relation of organisms of this character to disease is an extremely intricate one, and our readers will, long ago, have observed that whenever it has seriously come before us, we have felt it our duty to deal with it with the greatest caution; and, as regards cholera, we feel that, if possible, we ought to emphasise our caution. So far as experiments with animals are concerned, all the attempts hitherto made to induce unequivocal cholera symptoms in them by means of choleraic material, no matter how introduced into their system, have signally failed. The most plausible approach to success was obtained by Professor Thiersch, when he fed mice with fragments of blotting-paper which had been soaked in choleraic dejecta. These experiments materially influenced the decisions of the Vienna Cholera Conference, and carried much weight for some years, until, in fact, it was demonstrated by Professor Ranke that symptoms, similar to those described by Thiersch, might be induced in such sensitive little animals as mice, when they were fed with even unsoiled filtering paper. This is a lesson which the profession should not lightly forget.

In the absence, therefore, of thoroughly substantiated evidence of the existence of a specific cholera-germ Dr. Hunter proceeds "to draw attention to certain broad facts which confirm the results hitherto arrived at by

scientific investigation, and tend to the conclusion that in cholera we have to deal with a non-contagious disease." He cites his own experience and the experience of many others in support of this view, and directs attention to the fact that statistics regarding 8,000 attendants on cholera cases which had been collected in India, went to show that these persons were not more liable to the disease than others living in the same locality. As regards the circumstance that during the recent epidemic in Egypt it had been observed that whilst none of the sisters who had nursed our soldiers contracted the disease, nine per cent. of the men of the Hospital Corps did, he remarks :—"The explanation of such a marked disparity in the number of attacks, not only as between the sisters and men of the Army Hospital Corps, but also as regards the number of men attacked in other hospitals, is to be found in *fear*, one of the most potent factors in the causation of cholera in individuals."

With reference to the geographical distribution of the epidemic, Dr. Hunter states that it did not, as generally stated, take a southerly course down the Damietta branch of the Nile, and then to Cairo, and then proceed in a northerly direction up to Alexandria, "but rather an erratic course, following no particular route either by water or by rail, and appearing in distant places on one and the same day," thus tending to the conclusion that the production and diffusion of the disease were the result of some general influence, and independent of any traffic routes. Considerable prominence is given in the report to various unusual atmospheric phenomena which were observed in Egypt as they have often been in India in connection with outbreaks of cholera, though it has not as yet been found practicable to give a sufficiently expressive name to these complex meteorological conditions. Experience in India has, however, shown that some men appear to be so sensitive to these as often to be able to recognise them even before a single case of the disease has been observed in the locality ; and in Egypt Dr. Hunter was informed by Surgeon Prendergast that some of the men at Ramleh, who had served in India, had "remarked that there was *Cholera in the air*, and it so happened that at 10 a.m. of the next day the first case was reported." Taking everything into consideration Dr. Hunter is of opinion that the disease is due "to a combination of certain conditions of a cosmo-telluric character of air, soil, and water, filth, being a powerful factor, as in Egypt."

The epidemics of 1865 and of 1883, presented many points in common, both as to season — June to August in 1865, and June to September (in Lower Egypt) in 1883—and as to locality, the different places being attacked about the same time in each epidemic ; but "the disease spread with rather less rapidity during the recent epidemic than it did in 1865, although facilities for travel had much increased. The outbreaks at each period corresponded to a Nile about its minimum level, and their cessation to a Nile advancing towards its maximum, or to what may be called the dry and wet season respectively.

We have given our readers an insight into Dr. Hunter's reports, which will suffice to enable them to see that he is decidedly of opinion that the disease was of local origin in Egypt, and his reference to the isolated cases which are registered periodically in most of the large cities of Europe, also shows that he is of opinion that it may be generated from local causes, in Europe likewise, under certain conditions. His advice, consequently, is not to trouble ourselves with attempting to frame regulations for keeping out an enemy, which, he believes, has never been demonstrated to consist of a transportible entity, but to make the most strenuous efforts to secure "cleanliness in every form and shape." The profession is greatly indebted to Dr. Hunter for the care and trouble which he has taken in the preparation of these important and able documents. That the views advanced are opposed to those which are, perhaps, more generally entertained, in no way detracts from the merit of the reports. On the contrary, the mere fact that he has the boldness to steer against the current is of itself an indication that he must have given serious thought to what he was writing about. We must refer such of our readers as are desirous for more information in connection with the subject to the work itself, which, though an official document, may be obtained for eighteenpence through any bookseller.

THE HOSPITALS' ASSOCIATION.

In these days of co-operation it is not wonderful that a desire for the mutual help which co-operation affords should begin to manifest itself among some few of the more active of hospital managers. That there are great difficulties to overcome, and that the task of hospital management is a growing one, will be readily acknowledged. On the other hand, it is widely felt that there is need of more careful organisation, and room for much improvement in many directions. That such an association may prove helpful, all will concede ; but if it is to do good work, it must be thoroughly representative in its constitution, and the objects in view must be clearly formulated. Under these circumstances, we can only regret that so few assembled at the Mansion House last week, when the Hospitals' Association was formally inaugurated. It struck us also as not a little strange that the four principal speakers in support of the association should have taken such different, nay, even such antagonistic, views as to the work and objects of the proposed association. The only point on which there appeared to be unanimity was as to the necessity of enforcing payment from hospital patients, seeking, if necessary, Parliamentary power to do so. Major Ross' thoughts ran on Parliamentary Bills and their supervision while passing. Sir Fowell Buxton wanted to see provident dispensaries established everywhere, and to control the location of hospitals about London. Sir Rutherford Alcock was scandalised at the thought that a quarter of the entire population went to the hospitals for gratuitous advice ; he pinned his hopes of reform on obtaining a Royal Commission to enquire into the subject, and hinted at the establishment of some central controlling authority. Mr. Timothy Holmes thought we should keep the management of the hospitals in our own hands. He regretted the gratuitous advice given at hospitals, because it prevented the establishment of provident dispensaries.

We have conceded that such an association is a desirable undertaking; but we incline to think that its inauguration has been somewhat premature. Major Ross explained that St. Bartholomew's, St. Thomas's, and Guy's Hospital, had all kept aloof until the objects of the association had been clearly defined. Would it not have been wiser to have formulated these objects and secured the co-operation of such powerful corporations before bringing the question forward? The speakers were selected, the resolutions cut and dried, and no important changes were anticipated in them; indeed, there was rather a tendency to smother discussion, and unduly hasten through the formalities without, at all events, any adverse criticism. Mr. Hardy wished to allow not only those who are "connected" with hospitals to be members of the association, but others who might be *interested* in their management; this, however, was objected to by a member of the provisional committee. In other words, the association is to be a close one—to consist only of representative members of hospital corporations. For what purpose, then, was the general public invited to the Mansion House? It would have been in all respects better to have had a private gathering, those only to be admitted who were eligible for membership. Of even greater importance would have been the more accurate formulation of the reasons which had led up to the proposed association in lieu of the generalities with which the meeting was favoured. The very limited attendance, both of medical and lay authorities of the metropolitan hospitals, we cannot but think, is a measure of the favour which the scheme meets with in its present imperfect condition.

Dr. Glover was not far wrong when he stated that the chief object which the association appeared to have in view was that of criticising the present system of working hospitals. And such criticism, we fear with him, would tend to produce greater evils than those it pretends to remedy, and would increase the difficulties, already great enough, which managers have to encounter in their often thankless task. The promoters of the scheme seem to have forgotten that they are dealing with private charities, and that those who maintain a hospital will conduct it on any plan they like best. They set out also with what appear to be foregone conclusions, and we cannot wonder that the movement is not at present very widely supported, or that the managing authorities of our largest charities hold aloof. This question of payment by out-patients is not so one-sided, or so simple, as Mr. Holmes and Sir R. Alcock seem to think. Several efforts have been made at the London Hospital, for instance, to detect impostures, and the net result, after much deliberation, is that no change is at present thought desirable.

Among the four-and-a-half millions who exist in and around London, there is a mass of over-worked, under-fed persons in the East of London, who, when sick or injured, have no sort of refuge but the hospitals, and whose means of payment, not for medicines only, but for the maintenance of the families dependent on them, cease absolutely the moment they leave off work. It may be that at St. George's Hospital, with its more refined surroundings, some patients who apply for gratuitous relief could really afford to pay. Mr. Holmes must doubtless have good ground for his very warm advocacy of the payment system. But this is a matter for the St. George's Board of Management, and not for the Hospitals Association. Each hospital must work out its own system, and accommodate itself to the needs of the neighbourhood in which it is situated. Before bringing their affairs before such an association, let hospital managers take care that every prominent abuse is thoroughly sifted and righted. They appear to think that waste and mismanagement do exist; what more could an association tell them? The knowledge that abuses exist is the chief point, for to be warned is to be armed.

It was interesting to hear that the Royal Commission, which had been asked for, had been refused not only by the present Home Secretary, but by the Home Secretaries of successive governments. We think that they acted wisely; for a case has not yet been made out. This country, and especially this metropolis, occupy an unique position as regards hospitals. The state does not provide a single institution of the kind; and if the present institutions—which exist on private benevolence—were to shut their doors, there would be no provision for the vast number of accidents, and cases of disease, to which such an enormous population as that of London is liable. The government may well hesitate before interfering with institutions which relieve them of such gigantic responsibilities, seeing, on the whole, how well they discharge their self-imposed duties. There are many ways in which the present management of our hospitals may be improved. In the first place, the medical staff must be allowed and expected to take part in the government of their hospitals, in which, at present, they are in most cases excluded from all participation, and, as a consequence, about which they are indifferent. The need of such a reform as this is palpable, and requires no association to enforce it. In the next place, do the Boards, as at present constituted, really consist of working members; or are they merely names, leaving to one or two of their number, or to the secretary, the whole or chief responsibility? Let all those who do not take an active part in the practical details of the management retire, and let the vacancies be filled up by others who will do so. Finally, before venturing to discuss questions at large and in public, let the present managers of hospitals carry out such reforms in their own institutions as are necessary, according to their own showing; where there is waste, or inefficiency, let it be suppressed; where there is abuse, let it be shown up. It will matter little, then, whether the Association be formed or not. The promoters of the Hospitals' Association have started with strongly preconceived notions; they appear to make no secret that reform and radical changes in the present system are among their more immediate aims; unfortunately, though they are all associated with hospitals, we are not aware that they have yet done anything to raise their respective institutions above the level of the ordinary mediocrity with which they are so dissatisfied. Until they accomplish something in this direction, we fear the association will fail to attract much attention.

MODERN OPERATIONS FOR CATARACT.

In his Lettsomian lectures, the last of which we publish to-day, Mr. Brudenell Carter utters a vigorous protest against the old system of invariably waiting for the ripeness of a cataract before attempting its removal, and gives a lucid description of the more modern methods of dealing with mature and immature cataracts. He draws for us a touching picture of the condition of the patient formerly condemned to wait for years before undergoing an operation—the most favourable result of which was often but to "enable the sufferer to see his or her pathway to the grave." Fortunately, however, the object now desired is maturity of the *cataract*, not necessarily of the patient; and this fact, among others, must be some excuse for those who are still old-fashioned enough to advise waiting. In the days of the flap-extraction, as Mr. Carter points out, maturity was an essential for success; but now it is so no longer. It must be understood, however, that the lecturer still prefers a ripe cataract for operation, "but the practical question is whether the difference between this, and something which falls short of it, is sufficiently marked to be, in the majority of cases, worth waiting for?" It is obvious that this difference will, *cæteris paribus*, be more marked the more the mature condition is fallen short of, and that there must be a stage of immaturity at which it would be unjustifiable to interfere. But when the patient is unable, even with the artificially dilated pupil, to follow his or her usual occupation, and when courage and health both begin to fail, we may often endeavour to restore sight without longer delay. In such a condition, Mr. Carter generally does a preliminary iridectomy, after the manner of Mooren, and extracts the lens a few weeks later. The iridectomy alone sometimes hastens the maturation of the cataract, while the author occasionally produces this effect by dividing the anterior capsule with a fine needle a day or two before the extraction. He lays down excellent rules for our guidance in reference to the kind of immature cataract which it is most safe to remove, and the sort of section best adapted for the different kinds. But, in our experience, the association of conditions demanding early interference is by no means common. Not infrequently the one cataract is so much in advance of the other, that the better eye still fits the patient for work when the worse is ripe for extraction; a great deal, in every such case, necessarily depending on the nature of the occupation. Many patients are not dependent on their own exertions for their living; and many of those who are, have friends ready to assist them. Again, while some are dissatisfied and suffer in consequence, many are contented, hopeful in the knowledge that the cause of their blindness is removable, and often even anxious that nothing should be done until it is "quite ready."

In his first lecture, Mr. Carter gives a brief history of the different operations that have been practised for the relief of cataract. Couching, the flap-operation of Daviel, the scoop extraction of Waldau, the modified linear extraction (with iridectomy) of Von Graefe, and Pagenstecher's operation of removing the lens in its capsule, are all passed in review. He has also thought it necessary to notice a practically extinct method of extraction, the disadvantages of which are obvious, introduced by a metropolitan ophthalmic surgeon of repute. However deserving of hostile criticism this operation may be, we still consider it undignified in a Lettsomian lecturer—unworthy of himself, of his lectureship, and of his audience—to resort to a comparison between it and what he calls the "marital method," where "the patients were mostly of the female sex, ... in whom the lens had been expelled from the eye by the smart application to the margin of the orbit of the clenched fist of a male companion."

In the case of a mature cataract, Mr. Carter employs the usual modified linear extraction of Von Graefe, but makes his iridectomy rather smaller than is customary. He is very particular in removing all cortical substance, even introducing a small spoon or scoop for this purpose when necessary. Before the operation of iridectomy, whether preliminary or not, our author always uses eserine. We are astonished to find him assert, that "at the present day the instillation of eserine, as a preliminary to iridectomy, has become almost universal." This is far from being the case in this country, at all events. The arguments adduced for its employment are three in number, viz.:—1st, by contracting the pupil, the iris is drawn out of the angles of the operation wound. Now, immediately on the anterior chamber being evacuated, the iris, whether previously under the influence of atropine or eserine, assumes the position of medium dilatation, and the drug is unable to re-assert itself until the aqueous is retained. This retention may exceptionally occur in about twelve hours after the operation; but even by this time the action of eserine will have ceased altogether, or at least, have become quite inefficient for the task of disengaging the iris from its already formed adhesions. Again, a preliminary iridectomy, if performed according to Mr. Carter's method, ought to have little or no tendency to leave entanglements of the iris. 2nd. When the lens is swollen during the development of cataract, so as to narrow the anterior chamber, the contracted iris coming between it and the knife protects the lens from being accidentally injured. Surely, however, the delicate vascular iris is not the sort of cushion we would desire to interpose between the lens and a sharp cutting instrument. 3rd. When the intra-ocular tension is somewhat heightened, eserine relieves the congestion of the iris, and often thus prevents excessive bleeding into the anterior chamber during the operation. Now, since eserine is known normally to *increase* the vascularity of the iris, it is hardly likely that its employment can even here materially diminish the flow of blood from the cut surfaces of this structure; while in all other cases its effect must be hurtful in this respect. Indeed, we are inclined to think that its constant use may account in some measure for the particular stress laid by Mr. Carter on bleeding into the anterior chamber as a complication during the operation.

In his last lecture we have a valuable account of the author's experience in regard to the use of anæsthetics, and of the complications liable to occur during and after operations. We note that he invariably prefers having the patient anæsthetised, and recommends

the usual alcohol, chloroform, and ether mixture for this purpose. His after-treatment does not materially differ from that usually adopted. On the whole, it seems to us that the tendency of Mr. Carter's teaching in these lectures is to encourage somewhat unduly the extraction of immature cataracts, and we can only trust that his advocacy of this principle may not lead to its too free adoption.

REPORTS OF SOCIETIES.

PATHOLOGICAL SOCIETY OF LONDON.

TUESDAY, FEBRUARY 5TH, 1884.

J. W. HULKE, F.R.S., President, in the Chair.

Sporadic Cretinism.

Mr. BOWLBY showed four specimens of this affection.—1. A very large male born at full term, lived one hour. Head large, well shaped, cartilaginous base normal. Back of neck occupied by masses of subcutaneous fat. Skin œdematous, semi-translucent. Thyroid gland absent. Upper and lower extremities very short, epiphyses large in proportion to shafts, and readily separated from diaphyses. Under the periosteum of many of the long bones was a soft white material of undetermined nature; the ribs presented an oblique fissure at their external ends. 2. A fœtus born at term, body of normal size. Head natural shape, cartilaginous base of skull natural. Extremities extremely shortened, epiphyses being normal and the shafts exceedingly short, no enlargement at epiphyseal lines, and no attempt at ossification in any of the epiphyses. Ribs short, anterior extremities enlarged and nodular. 3. Fœtus measuring twelve inches. Head broadly pyriform, enlarged in transverse and vertical diameters. Frontal, parietal, and occipital bones represented by a single continuous case of bone widely open in front and above, other cranial bones depressed, all light, dry, and porous. Ribs very thick. Extremities stunted, all the bones, including the phalanges, thick, heavy, and more or less bowed; epiphyses large in proportion to shafts; no swelling at epiphyseal lines. 4. Head natural, palate cleft. Forearms very short and curved; lower extremities also very short and somewhat curved; excess of digits on hands and feet.

The microscopical appearances in all the cases were very similar. In the epiphyseal cartilages the cells were not arranged in rows at the junction of the epiphysis with the shaft; there was no evidence of ossification at this point. Between the bony part of the shaft and the cartilage of the epiphysis was a well-marked layer of connective tissue continuous with the periosteum. This condition was present in the bones examined. Mr. Bowlby's specimens being all from a museum, he was unable to give any clinical details. Briefly reviewing his cases and comparing them with those recorded by Dr. Hilton Fagge, Dr. Barlow, Mr. Shattock, and others, he noted that in none of his cases was there any premature synostosis of the basilar process with the sphenoid bone. In his first case the thyroid gland was absent, and there was a great excess of adipose tissue at the back of the neck, though there were no definite fatty tumours. The other cases afforded no evidence on either of these points. The chief interest in his specimens, however, lay in the extreme shortness of the bones of the extremities, and this he attributed to the ingrowth of connective tissue at the junction of the epiphysis with the diaphysis. As to the proximate cause of this, after referring to the admitted resemblance between cretinism and myxœdema, he suggested that in sporadic cretinism, and perhaps also in the endemic form, there might be a tendency in the connective tissue of the periosteum to over-growth, and proceeded to point out that it had been noticed that after the removal of the thyroid gland in young people growth had been arrested, and a condition akin to myxœdema produced. The curvature of the bones he attributed to the very early stage at which the interference with growth took place; the earlier this commenced the more curved the bones, and vice versâ.

Fœtal Rickets (? Cretinism).

Dr. BARLOW exhibited a specimen very closely resembling one that he had brought forward during the debate on Rickets. The limbs were stunted, their chief feature being the defective row formation in the primordial cartilage, in consequence of which the earthy salts deposited in the process of ossification did not present their usual arrangement. The growth of the bones was limited as to their length, but those formed from membrane (*e. g.*, clavicle) were well developed. The epiphyses of the long bones were only relatively large, there was no proliferation of cartilage along the line of ossification as in ordinary rickets. Along the upper line of ossification was a layer of fibrous tissue, arising from the periosteum. The ribs were not beaded as in rickets, but there was an investing sheath of bone round the end of the costal cartilage. There was premature synostosis of the basi-occipital, basisphenoid and præsphenoid, the cartilage forming part of the occipital bone was stunted, whilst the membrane-formed part was normal. The cerebellar fossæ hardly existed, and the cerebellum was very ill-developed, and pushed forwards and upwards. At the base of the brain the under-surface of the temporo-sphenoidal and occipital lobes and uncinate convolution showed a deep fissure which passed upwards and forwards to near the middle of the temporo-sphenoidal lobe terminating near the posterior limb of the fissure of Sylvius. The fissure was symmetrical on the two sides, and was probably due, in part, at any rate, to the pushing upwards and forwards of the cerebellum already alluded to. As to the other viscera, the heart showed funnel-shaped aortic and pulmonary orifices, a patent foramen ovale, an imperfect septum ventriculorum and no mitral orifice. The thyroid gland was normal, there were no separate fat masses in the neck, but much heaping up of subcutaneous fat throughout the body. Without denying the existence of fœtal rickets, he (Dr. Barlow) was anxious to insist on the distinction between this group of diseases and true rickets. It was a vice of conformation, not a change of nutrition that was the cause in the disease under consideration. He referred to a case in which there had been premature union of the frontal and parietal bones with the occipital bone, and Virchow had alluded to similar cases. Comparing his cases with those recorded by Dr. Fagge, he noted that the dwarfing in the latter was not so prominent a feature as in his own cases. The absence of the thyroid was not an essential feature of the disease; in the specimen he brought forward that evening, the thyroid was normal, and in one of Dr. Fagge's cases, after death a small goitre was discovered, while during life the thyroid had been supposed to be absent. The fat masses were not necessarily always present. In conclusion, Dr. Barlow pointed out the necessity for further microscopical examination of the ends of the long bones.

Mr. J. B. SUTTON, said that no history could be obtained of the specimen he brought before them. One half of the body had been dissected to display the skeleton, the remaining half had been left to show the external characters of the

fœtus. Concerning the exterior, the noteworthy points were its extraordinary size, the very large head, and the thick, but short, stunted limbs. It was a female. The fœtus measured from the crown of the head to the sole of the foot, 20 inches. Of this 6½ inches represented the head, 9 inches the trunk from foramen magnum to tip of coccyx, and only 4½ inches the legs. In an ordinary fœtus, he said, at birth the head should measure one-fourth of the whole body, whereas in this specimen the head equalled more than one-third the body. The arms should reach to near the middle of the thigh, but in his specimen they were on a level with the umbilicus. The skin of the limbs was wrinkled in transverse folds, and there was an excessive quantity of fat in the subcutaneous tissue all over the limbs, trunk and face. The only visceral lesion noted, was enlargement of the thyroid gland to twice its usual size. The skull presented a curious appearance. Its base was very short, due to synostosis of the basilar suture. The foramen magnum was very narrow, and in shape elliptical, with its major axis transverse to the squamous portion of the pelvous bone, the occipital bulged backward at the seat of the torcular herophili, so that it presented, on the inner aspect, a deep cup-shaped depression, where the four centres for this portion of the occipital bone become confluent. The floor of the cranium was divided into shallow fossæ by strong ribs of dense bone. All that portion of the skull which arose in membrane was enormously exaggerated, the bones being extremely thin and deficient, the chief part of the vertex being formed of stout membrane as in hydrocephalic infants. The ventricles of the brain were greatly distended with fluid. The ribs were broad, the intercostal spaces narrow, so that the capacity of the thorax was small, the beading of the rib shafts at their junction with the costal cartilages was obvious. The clavicle was rather long, but not otherwise deformed. The scapulæ were thick and stunted, the bones of the arm presented short thick shafts, with very large terminal cartilages. The ossa innominata were thick and stunted, and the bones of the leg presented similar characters to those in the upper limb. There was no earthy spot for the condyles of the femur. In sections carried through the junctions of the shafts of the long bones, with their terminal cartilages, the following changes were seen. 1. There was absence of the familiar rows of cells so constantly seen where hyaline cartilage was undergoing conversion into bone. 2. Between the bone shaft and the cartilage cup, a line of fibrous tissue was seen, continuous with the periosteum. The condition of the skeleton might be summed up thus:—There was an overgrowth of membrane bone, with lack of cartilage metamorphosis. It seemed as though membrane and cartilage, instead of harmoniously working together to form bone, had broken alliance with each other, and pursued their own course to each other's detriment.

The PRESIDENT spoke of the great interest of the subject.

Dr. GOODHART showed photographs of a cretinous boy, eleven years old, showing marked fatty masses in the neck.

Dr. MAHOMED alluded to three cases under his own care. A girl, aged fourteen, with large square head, very stunted limbs, but intellect good. The others were two members of the same family, intelligent, but with stunned limbs and overgrowth of the connective tissue.

Fibroid Disease of the Heart.

Dr. HALE WHITE read a paper in which he reminded the Society that it was just ten years since Dr. Hilton Fagge read his exhaustive paper on this subject. During this period, nine cases had occurred at Guy's, in which the only cause for sudden death was this condition of heart. Dr. Hale White related a typical case in which a man fell down suddenly in the Borough, on being brought to Guy's, the only cause for death was fibroid disease of the heart, which was probably syphilitic, as other evidences of this disease were present. Sections of the heart from this case were shown under the microscope. The great importance of fibroid disease of the heart, as a cause for unexpected sudden death, was pointed out, and, inasmuch as nine cases had happened at Guy's Hospital, it might be taken that Dr. Fagge's prophecy, that this would be found to be a common cause of sudden death was proved. With regard to syphilis, this was present in four out of the nine cases so that we must now look upon sudden death as one of the effects of this disease. In the remaining five cases there was nothing to show what was the cause of the fibroid disease, nor were there symptoms to point to it during life, in fact, in most cases, it was definitely stated that at the time of death, the patients were in the best of health.

Carcinoma of Œsophagus.

Mr. SAMUEL BENTON shewed this specimen, taken from a man of intemperate habits, who had a stricture of œsophagus for fourteen months before death There was no thirst, and he was able to take sufficient nourishment, so that gastrostomy was unnecessary.

Mr. BUTLIN said this was a case of hard spheroidal celled carcinoma, not epithelioma, wall of œsophagus infiltrated, there was less ulceration than in epithelioma, and it ran a quicker course than ordinary cancer. There were secondary nodules in the pericardium.

Mr. CLEMENT LUCAS asked what had been the cause of death?

Mr. BOWLBY referred to a case where there was a hard cancer of the œsophagus, with no glandular enlargement, and no secondary growths; the patient died of septic poisoning, after gastrostomy had been performed.

Mr. BUTLIN stated that the patient had died from inanition.

Growth from Bladder.

Sir HENRY THOMPSON observed that these tumours were much more common than had been formerly thought. This one was the sixteenth case he had operated on. The patient was 44 years old, and had had hæmaturia for six years in 1881. The operation was performed last autumn. Ten or eleven of the growths were villous. The symptoms were slow and gradual, often with distinct onset from local irritation. In most, the growth was homologous with the tissues of the bladder. Two of them were cases of epithelioma, the others were of a malignant nature. He did not operate where there was infiltration of the bladder. There had been no recurrence in his two earliest cases, operated upon three, and two and a half years ago. In several there had been recurrence, and he had operated a second time in some of them.

Mr. BUTLIN had examined a tumour removed from the bladder, consisting of a fibrous base, covered with epithelium. In this case the growths recurred, and there were a number of sessile vascular growths; they were found to be round-celled sarcomata, he could not be certain that these were recurrences of the original growth.

The PRESIDENT said he had had three cases in the hospital recently: one of them was an epithelioma, and infiltrated the bladder; the second was a papilloma, too extensive to be removed; the third also of papilloma, and was not altogether within reach, and therefore was not altogether removed.

Sacculated Calculus in the Bladder.

Sir HENRY THOMPSON mentioned the case of a woman, æt. 42, on exploring the bladder with the finger, there was a firm smooth growth springing from the base of the bladder, almost pedunculated; on grasping it with forceps, he discovered a calculus, which he then enucleated. Sacculated

calculus was decidedly rare, but he had met with three other cases during life, and had removed them.

Mr. BLACK had seen a case where a calculus, impacted in the ureter, had simulated a sacculated calculus.

Mr. THOMAS SMITH alluded to a case he had exhibited to the members of the Society, where each ureter was blocked by a stone, and prolapsed into the bladder.

Mr. CLEMENT LUCAS mentioned cases similar to these, that had already been published.

Sir HENRY THOMPSON thought there was no room for confusion between a sacculated calculus and an impacted calculus in the ureter.

Mr. THOMAS SMITH said, that in his patient there had been no symptoms of suppression of urine, and there was no hydronephrosis.

Pigmentary Degeneration of Tongue.

Mr. G. STOKES said this was a case of "black tongue." The man had noticed it first three years ago, and the condition was spreading. The fungiform papillæ were greatly swollen, as shown by a microscopical examination.

Card Specimen.

The PRESIDENT.—Two drawings of rodent cancer of the face.

Dr. LEDIARD.—Epithelioma of foot.

Mr. BOWLBY.—Dermoid cyst of the finger.

Dr. HALE WHITE.—An infiltrating tumour of the bladder.

OBSTETRICAL SOCIETY OF LONDON.

MEETING, WEDNESDAY, JAN. 9, 1884.

DR. GERVIS, President, in the Chair.

The late Mr. B. R. Wheatley.

THE PRESIDENT announced to the Society the death (which had taken place that day) of Mr. B. R. Wheatley, who had acted as their assistant secretary from the foundation of the Society till about two years ago. A vote of condolence with the relatives of the late Mr. Wheatley was moved by DR. MATTHEWS DUNCAN, seconded by DR. PLAYFAIR, supported by DR. PRIESTLEY, and carried.

Hysterectomy.

Mr. KNOWSLEY THORNTON showed an enlarged uterus, surrounded by multiple fibroids, the right ovary and tube attached, the stump of a large fibrocystic tumour of uterus (also shown), and a partly calcified fibroid, of the size of a fœtal head, which had to be enucleated in order to apply the serre-nœud. The parts came from a single woman, aged 55, from whom, on account of excessive hæmorrhage and rapid growth of the tumour, they were successfully removed.

Hæmato-salpinx.

Mr. KNOWSLEY THORNTON also showed the ovaries and tubes removed from a married lady, aged 29. She had suffered from repeated hæmorrhages, which followed a severe emotional shock; and tumours were discovered to the left and right of the uterus. These were removed, and proved to be the tubes, full of tar-like blood and firmly adherent. There was also an ovarian cyst with commencing papillomatous growth. After removal of the diseased parts, the discharge gradually ceased, and the patient did well. Mr. Thornton thought the case either one of tubal pregnancy, or of hæmorrhage the result of emotional shock, the blood being prevented from escaping.

Pelvic hæmatocele from malignant disease of peritoneum.

Dr. PLAYFAIR exhibited this specimen, taken from a girl of 16, from whom he had removed an ovarian tumour in April, 1883. At the end of November she was admitted into King's College Hospital, with symptoms and signs of a retro-peritoneal hæmatocele so large as to compress and obstruct the bowel. This was first aspirated, then freely incised and drained, with immediate but temporary relief to symptoms. On autopsy, the peritoneum was found studded with masses of soft cancer, one of which had ruptured and caused the hæmorrhage. No trace of the ovariotomy ligature could be found. He had not seen recorded a case of hæmatocele from such a source. He believed its association with the ovariotomy to be only that of coincidence.

Observations on puerperal temperatures.

This paper, by Mr. E. S. TAIT, M.B., was then read.

The patients observed were in the General Lying-in Hospital: 60 were primiparæ and 65 multiparæ. The day after delivery on which the highest temperature most often occurred was the third, then the fourth, then the second. In 25 cases the highest temperature occurred during the second week, often from nervous causes. Lacerations of the perineum did not appear to affect the day of highest temperature. Mechanical interference during labour did not seem to affect the result. The average temperature was lower in those cases in which there was no tear than in those in which deep lacerations had occurred. In primiparæ the temperature appeared to be raised by labial tears, deep perineal tears, and the use of forceps; but in multiparæ no such effect could be traced. Slight perineal tears seemed to scarcely affect the temperature. The introduction of the carbolized hand into the uterus during the third stage did not affect the average temperature. In six cases there were urticarious or erythematous rashes, which did not affect the temperature. The temperature was highest in the latter part of the day, lowest in the early morning. When the 10 p.m. temperature was higher than that at 6 p.m. there was often inflammation present. The temperature frequently rose without any physical cause to account for it; and in such cases it was often found that something had happened to disturb the patient's nervous system, such as fright, bad news, &c. Accounts were given of instances of such "nervous temperatures," as they might be called.

Dr. ROUTH said, that in disease the temperature might be as much as three degrees hotter in the vagina than in the axilla. Unless therefore the temperature, in the puerperal state, were taken in each part, error might follow.

Dr. JOHN WILLIAMS thought that Mr. Tait had established two facts: that high temperatures were more common when the perineum had been deeply torn, and that high temperatures were associated with nervous conditions during the puerperal state. It was frequently said that tears of the cervix were causes of fever; he (Dr. Williams) thought they were rarely so. The relation of fever to fœtid discharge was important; in many cases the fœtor came on after the fever and not before it, and might therefore be inferred to be its result and not its cause.

Dr. GALABIN thought it would be of interest to compare, if possible, the temperatures observed in private practice with those of hospital patients. His own impression was that the range of temperature was not so high as that observed by Mr. Tait. He doubted whether, in cases of rise of temperature, apparently from nervous causes, such causes were always unmixed. It might be combined with some septic disturbance. He related a case in illustration.

Dr. GRAILY HEWITT thought the facts brought forward as to rise of temperature from emotional conditions most important. He mentioned a case in illustration. He suggested that it was probably due to temporary relaxation of the uterus, and consequent absorption of septic matter.

All that he had ever seen favoured the idea that the septic material was absorbed before the fever began.

Dr. DALY thought that fœtid discharge preceded and caused fever. This was proved by the effect of treatment. He thought the range of temperature was, as a rule, higher in hospital than in private practice.

Dr. PLAYFAIR had, time after time, observed in private practice, cases of high temperature in which he was satisfied that Mr. Tait's explanation, that they were due to emotional disturbance, was the true one. It was important to distinguish these from the more serious pyrexia due to septic mischief. In the latter an initial rigor was rarely, if ever, absent. Nervous high temperatures were not confined to the puerperal state; and temporary high temperature might be produced in the puerperal state by other than nervous causes. He knew of no facts to justify Dr. Williams's theory of the relation between fœtid discharge and pyrexia; and he hoped no one would be induced by it to underrate the importance of fœtid discharges, for no woman could be considered safe in whom such existed.

Dr. GODSON mentioned a case of pyrexia due to an emotional cause. He considered it exceptional for rise of temperature from such cause to be preceded by a rigor.

Dr. PRIESTLEY said the records in the paper of pyrexia demonstrated to be due to emotional causes showed the importance of shielding the puerperal woman, not only from physical but also from mental disturbance. They also showed that high temperature was but a unit among other symptoms, and, unless accompanied by rigor, abdominal tenderness or other signs, did not invariably indicate danger.

Dr. MATTHEWS DUNCAN called attention to the value of a regularly constructed chart, as against isolated observations. He was sure that in private practice, as great variations of temperature occurred as in hospitals. All his ideas were unfavourable to the reception of the doctrine that the fever caused the putridity of discharge. Putridity was not an essential part of the worst kind of infecting material. Infection by putridity began with the taking in of the poison, and ceased within a few hours after stoppage of the supply. This was sapræmia, without septicæmia.

Dr. CHAMPNEYS said that about the third day, on which the milk, the bowels, and surgical injuries combined to raise the temperature, diagnosis was very difficult, often impossible. Pelvic inflammation, which was often quite ephemeral, could not be excluded without vaginal examination, which had been made in the cases recorded in the paper. The evidence he had, although small in amount, of cases in which regular and frequent observations were made, showed that the range of temperature in private practice was as high as that in hospitals. The proof that "nervous temperatures" were not septic was that they only lasted a few hours, and that no infection of other patients took place. The mortality in good lying-in hospitals was becoming less than that in private practice. Fœtor of discharges was useful as a means of attracting attention.

Dr. WYNN WILLIAMS said that if septic matter came in contact with a wound and was absorbed, it was followed by rigors with diminished temperature.

The PRESIDENT said that from his experience in private practice, and from observations made in St. Thomas's Hospital Maternity Charity, he believed the average temperature in private practice was not so high as that of Mr. Tait's cases. He could quite understand that in the class of cases in which infection was brought from without, offensive discharge due to necrotic endometritis might follow and not precede the fever.

Mr. TAIT said that the observations of higher temperatures in hospital than in private patients he thought due to the greater frequency and regularity with which the temperature was taken in the former class of cases. Dr. Hewitt's explanation of the "nervous temperatures" he thought was negatived by the great rapidity of the rise and fall of the temperature in these cases. In many of them the patient looked and felt well, so that the rise of temperature would have passed unnoticed had it not been for the diligent use of the thermometer.

SOCIETY OF MEDICAL OFFICERS OF HEALTH.

FRIDAY, JANUARY 18TH.

Dr. DUDFIELD, President, in the Chair.

Sanitary Work at King's Lynn.

MR. W. G. WALFORD read a paper, entitled "Nine Years' Stewardship as Medical Officer of Health at King's Lynn, its Difficulties and Results, with special reference to the Improvement of the Dwellings of the Poor." Mr. Walford took office in 1873. The town had at that time a population of 17,000, and presented the same wretched slums, poverty, overcrowding, misery, and vice as other towns of its size. For a year or so previously, an agitation, similar to that which is now going on in London, had been engaging the attention of the public and the local press, and a severe epidemic of scarlatina had prepared the minds both of the authorities and the people to acquiesce willingly not only in every sanitary improvement, but in the adoption of the notification of infectious diseases, the results of which were so satisfactory, that the fever almost disappeared for several years. Quite recently, however, the immunity enjoyed so long led to indifference, and on its breaking out again, the mortality was rather high, in consequence of the difficulty Mr. Walford then experienced in enforcing proper measures. From the first, he found the authorities always ready to put in force the various Acts relating to the dwellings of the poor, some of which had not been carried out with anything like the same thoroughness elsewhere: they paid the poor-law medical officers half-a-crown for every case of infectious disease or nuisance reported by them, and, thanks to the hearty co-operation of the district-visiting ladies, the police, and medical men generally, very few, if any, abuses could escape his notice. He also, accompanied by the borough surveyor, made regular and frequent inspections of his district. He found that it was easy to divide the poor into two classes—those who would, and those who would not, help themselves—the former gladly availing themselves of every improvement and means of bettering their position, while all such help was absolutely thrown away on the latter, who, in several instances, having been located in new houses, or in old ones that had been put in complete repair, immediately wrecked them, by using for firewood every piece of woodwork that they could tear away, and more often than not paid no rent. Lynn being a manufacturing and seaport town, there was always plenty of work to be had, and rents were lower than in many similar towns, so that he was forced to the conclusion that the wretched homes and condition of many of the poor was mainly, if not entirely, the consequence of their own improvidence and habits. Overcrowding was, he must admit, with many of the poor, merely a question of the relation between wages and rent. If a man had a large family and no regular work, or was in ill-health, it was impossible for him to afford such accommodation as sanitary requirements would demand, and it was equally impossible to drive him into the workhouse or street, or to give him a better house. Overcrowding resulting from the admission of persons for a night's lodging into rooms already fully occupied was most difficult to deal with, because difficult to ascertain. Even if the landlord ejected a family known to harbour such casual lodgers, they would only remove the evil to another quarter. As the general result of his experience, Mr. Walford considered that the existing Acts were amply sufficient to meet these various evils, so far as they could be remedied

by legislation, and he could confidently say that very great improvement had been effected during his tenure of office in the dwellings of the better class of poor; but as to the improvident and vicious, very little success had been achieved, or, indeed, could be, unless a policeman were stationed day and night at the doors, to watch over the conduct of the occupants of each house and room!

In the discussion which followed, the President, Drs. Tripe, Moore, Dixon, Armistead, and Waterworth, and Messrs. Corner, Lovett, and Wynter Blyth took part, giving their own experiences in their respective districts.

ABSTRACTS AND EXTRACTS.

Da Costa on Quebracho.—In a recent lecture, Professor Da Costa says that he has found this drug especially serviceable in two classes of cases:—(1) In purely nervous asthma he had found it invaluable; (2) he had also known it to be very useful in cases which have been rather loosely called cardiac asthma—cases in which a heart lesion has produced failure of cardiac contraction and consequent congestion of the lung. He prescribes it in twenty-minim doses of the fluid extract every hour, gradually increasing the amount—some patients requiring as much as a drachm before relief is obtained. The good effects are usually observed after two or three doses have been taken; as the respiratory symptoms are relieved, the remedy may be given at longer intervals. The taste is well covered by using as the vehicle equal parts of the French syrup of red orange and water.—*Boston Med. and Surg. Jour.*, Dec. 27, 1883.

Voluntary Luxation of the Hip-Joint.—Dr. J. N. Hall reports the case of a telegraph operator, 40 years of age, who has since childhood been able to dislocate the right hip by a muscular effort at will. After sitting for a time in the usual posture, he throws the head of the femur on to the dorsum ilii, inclines slightly to the right side, and brings the weight of the body to bear on an almost entirely new surface; when fatigued, a second muscular effort replaces it, and he resumes the usual upright position. A well-marked sound accompanies the displacement from the acetabulum. Other joints are normal, although the ligaments of the thumb are relaxed.—*Boston Med. and Surg. Jour.*, Dec. 27, 1883.

Sarcoma of the Rectum.—The patient, a man æt 43, gave a three years' history of dyschezia. Of late, evacuations had been secured only by purgatives and enemata. Hardened fæces were occasionally the cause of some bleeding from the rectum. Two years previously he had suffered with an inflammatory trouble in the perinæal region, and with retention of urine. One year ago, on introducing his finger within the rectum to relieve the tenesmus, he detected a small tumour, which was then the size of a walnut. When the man came under observation, this tumour had attained the size of the fœtal head; by an expulsive effort the mass could be made to appear outside the sphincter ani. Upon examination, the growth was found to lie beneath the mucous membrane of the bowel, having its origin in the submucous structures to which it was attached, or in the connective tissue. Dr. Levis grasped the tumour with strong hooks, pulled it downwards and easily enucleated it. After removal it was found to be rather dense and elastic; it measured nearly three inches in diameter, and weighed twenty-four ounces. Microscopical examination showed it to be a spindle-cell sarcoma, making it one of the rarest growths in this situation.—*Boston Med. and Surg. Jour.*, Dec. 27, 1883.

Iodoform Dressings.—Iodoform is a very good dressing for small lacerated or contused wounds (of the skull, *e.g.*). There is only one objection to it—the possibility of producing slight dermatitis; and this can be guarded against, by a layer of sublimate gauze directly over the wound.—*New York Med. Jour.*

Modified Small-pox Inoculation. — During the American Civil War, a medical officer of the Confederate Army found himself face to face with an outbreak of small-pox, and without any supply of vaccine, or the possibility of obtaining it. Under these circumstances the idea occurred to him that he might, so to speak, make it: he mingled small-pox virus with cow's milk, and with this mixture of milk and variolous matter he inoculated his men, and the result was in every way satisfactory. Not only did he shield his force from a murderous spread of the unmitigated disease, but he also confirmed his theory in his own estimation. As a consequence of the latter circumstance, the experiment has lately been brought into notice again, and its repetition has been suggested as a legitimate and trustworthy method of obtaining a good quality of vaccinal material for future use. We must say that the probability is vastly strengthened, that he who inoculates with small-pox virus, "modified" or unmodified, really spreads small-pox and nothing else. With this conviction, we must urge the utmost caution as to experiments in "modified inoculation."—*New York Med. Jour.*, Dec. 22, 1883.

Hystero-Epilepsy Complicating Pregnancy.—In the *New York Med. Jour.*, Dec. 22, 1883, Dr. W. H. Shipps relates the case of a young married woman, æt. 18, in whom the "hystero-epilepsy with combined crises" of Beau, devoloped during the third month of a first pregnancy. From the occasion on which she was first seen—early in March, 1883—until her delivery at term in the following September, not a day passed without the occurrence of one or more paroxysms. The attacks appeared to resist all medicinal treatment. Since the birth of the child the fits have not recurred.

Kerosene Poisoning. — A child, 18 months old, swallowed an unknown quantity of kerosene, probably not more than two ounces. When seen one hour afterwards, the patient was vomiting, purging, cyanotic; there was a tendency to coma, pulse 130, weak, irregular; respiration irregular. The treatment comprised first ordinary emetics, then stimulants and alkalies. After a few days of gastro-enteric febrile movement, the child recovered. Several ounces of kerosene are said to have been taken by adults without perceptible results.—*N. Y. Med. Rec.*, Dec. 29, 1883.

Nitrite of Sodium.—At a recent meeting of the Société de Biologie, M. Hénocque made known some interesting researches on the physiological action of nitrite of sodium. By spectroscopic examination of blood, he found that under the influence of this drug hæmoglobin temporarily lost its power of uniting with sufficient oxygen to convert it into oxyhæmoglobin; in other words, oxidation in a minor degree only is possible. He regards the action as comparable to asphyxia produced by carbonic acid, rather than that resulting from carbonic oxide, since the effect passes off by degrees, and the corpuscles resume their functions in course of time. —*Gazette Hebdomadaire de Paris*, Jan. 4.

Dislocation of the Foot Forwards and Outwards. —The *New York Medical Record* for Dec. 8, 1883, reports a case of this rare accident as follows:—"On July 20, 1883, the Rev. Mr. Y——, æt. 60, height 6 feet 2 inches, weight 200 lbs., while in the loft of his stable, attempted to descend by a stationary step-ladder to the floor below. He lost his footing and fell a distance of eight feet, striking first the lowest step of the ladder with his left heel, dislocating the ankle (foot) *forwards;* and then, after the rebound, struck the floor with the outer side of the foot, throwing the ankle (foot) violently *outwards*. When first seen, the foot was in a position nearly at right angles to its true one. The internal malleolus was at the inner border of the plantar surface of the foot, and strongly pressing against the scaphoid bone; the outer malleolus formed a prominent bony tumour at the outer side of the heel, and the articular surface of the astragalus was two inches in front of the outer malleolus, and pushing the skin of that part of the dorsum of the foot on which it impinged out to such

an extent as to be on the point of penetrating it, having forced its way through the ligaments, fascia, and tendons, until nothing but the skin itself stood in the way of the injury being a compound luxation. There was no fracture of either malleolus. Two hours after the injury the patient was etherized. Owing to the peculiar deformity, it was not deemed advisable to follow the usual method of reduction, *i.e.*, to flex the leg and then extend. The leg was kept extended and held firmly by an assistant while the heel was grasped by the right, and the dorsum of the foot by the left, hand, and forcible extension and manipulation were made. The foot was twisted in such a manner as would compel the astragalus to retrace the path it had made in getting into its abnormal position through the soft parts. In this manner the reduction was perfectly effected without very great difficulty. A roller was firmly applied and side splints put on. Hot applications were freely used and hot-water baths every day. The foot was rubbed and kneaded to prevent solidification of effused material, and the limb was elevated. On the twenty-second day the patient was able to use crutches; on the thirty-sixth he walked with a cane; and now, ten weeks after the injury, he goes without the cane, does not limp, and there is no swelling or stiffness of the joint."

PARALDEHYDE AS A HYPNOTIC.—Dr. J. C. Wilson, in the *Maryland Medical Journal*, gives his experience of the use of paraldehyde. The average dose for an adult he states to be a fluid drachm, given with a considerable draught of water on account of the unpleasant taste and odour. He has employed it with success in nine cases, but he states that several patients complained of the disagreeable after-taste. He concludes that it may form a useful addition to the ordinary hypnotics, but that it is not likely to supersede them; one great disadvantage is, that it appears speedily to require an increase of the dose.

LARGE VESICAL CALCULUS.—The patient, whose case is reported in the *Boston Med. and Surg. Jour.*, Dec. 27, 1883, was a female, æt. 38, and had been insane for over two years. A bent hair-pin, which she had introduced into the nostril, "with the object of dislodging a skunk" (she was subject to hallucinations of hearing and smell) was extracted through an incision made between the nasal bones. Soon afterwards, under the impression that some animal was lodged in the bladder, she introduced into the urethra a hair-pin, which was carried beyond her reach into the bladder; this was subsequently voided encrusted with urinary salts. A little later she introduced two hair-pins in the same way; the pain to which they gave rise at length compelled her, six months afterwards, to disclose the facts; and a calculus which weighed 950 grammes (*sic*) (30¾ ounces!), and presented the two points of a hair-pin lying towards the neck of the bladder, was extracted by an incision through the vesico-vaginal septum. The bladder-wall was already ulcerated, and at one of these points perforation into the abdominal cavity took place, the patient dying on the sixth day of peritonitis. The nature of the calculus is not stated, but it was probably phosphatic; and in the report of the case "grammes" appears to be a misprint for "grains."

SPINA BIFIDA WITH VERY LARGE TUMOUR.—Dr. M. D. Briggs reports a case of spina bifida, in which the tumour, which was about as large as an orange at birth, had, at the end of ten months, attained such a size as to measure 30 inches in its longest circumference, and 26 inches transversely. It was translucent, and filled with straw-coloured fluid. In a few days it ruptured, and the child died five days afterwards with meningeal symptoms. No post-mortem was obtained.—*N. Y. Med. Rec.*, Dec. 29, 1883.

INVERSION OF THE UTERUS, DUE TO TRACTION ON THE CORD.—Dr. Geo. Huntington, called to a case of labour, found the woman dead on his arrival. After the birth of the child, an ignorant midwife had made such traction on the cord as to invert the uterus. The woman died of hæmorrhage in less than an hour.—*N. Y. Med. Rec.*, Dec. 29, 1883.

CONGENITAL GOITRE CURED BY ONE APPLICATION OF MERCURIC IODIDE OINTMENT.—Mrs. B., healthy, had a slight goitre which had been first noticed during her previous pregnancy, about two years before. Her second child, born July 26th, 1883, exhibited a congenital goitre, the size of a hen's egg, soft and fluctuating, on the right of the trachea. Treatment was deferred until the child was three months old, when the tumour had grown so as to fill the whole space between the child's chin and sternum on the right side; it interfered with respiration when he lay on his back; the flattening of the crown of the head (Aitken) was now well marked. Mercury biniodide gr. x, and lard ʒj was ordered—a piece the size of a filbert to be well rubbed into the skin, over the whole tumour, at 10 a.m., on a bright sunny day; the child then to be held to the sun at a closed window (the weather being cool) for half-an-hour, and then in front of the fire for an hour; the application and exposure to be repeated at 2 p.m., on the same day. This was done on one day only, causing much pain and cutaneous irritation; but the tumour shrank rapidly, and in ten days' time the thyroid gland was just palpable and of the normal relative size. There was no salivation or other indication of constitutional disturbance.—*N. Y. Med. Rec.*, Dec. 29th, 1883.

THE CONSOLIDATION OF FRACTURES IN DIABETES.—Dr. Verneuil, writing on this subject (*Bull. de l'acad. de Med.*, 1883. No. 30), says that the striking points are the very slight reactive powers; callus is either absent or deficient, and consolidation is deferred. Also very little pain is felt—so little that the abnormal absence of pain makes the author suspect the presence of diabetes.—(*Centralblqtt für Klinische Medicin, Jan.* 19, 1884.)

GENERAL CORRESPONDENCE.

CONSULTANTS AND GENERAL PRACTITIONERS.

[To the Editor of the Medical Times.]

SIR,—I am obliged to "M.D." for noticing my letter, and will willingly do anything in my power to make it clearer; but I do not yet quite understand against whom his argument is directed, or whether he intends to credit me with the formidable propositions of which he asks a proof at my hands. A consultant, in ordinary practice, is one who makes a business of giving opinions in doubtful or difficult cases. Possibly "M.D." thinks there should be no such people. They exist, however, and presumably in compliance with an actual demand. "M.D." further denies that school and hospital men are fit persons for the work. I need not occupy your space with discussing this question on its merits; it is matter of fact that the great majority of the profession have arrived at an opposite view. They have decided that men trained in school and hospital work are the persons most likely to possess the particular kind of knowledge desirable in a consultant, and have thrown the bulk of consulting work into their hands. As school teachers are in consequence recruited from the *élite* of the profession, their position is not exactly comparable to that of a modern drawing master, as "M.D." would have it. "M.D." should not have forgotten that Titian and Tintoretto, Rembrandt and Rubens were "Masters" too. I certainly consider that the interests of the public, the profession at large, and the consulting body, would be better met by an adherence to strictly consulting practice on the part of, at least, the well-established consultants; but it does not, therefore, follow, as "M.D." seems to think, that a physician or surgeon is *not* a consultant, unless he does so restrict himself. Into shadowy questions of superiority and status I am unable to follow "M.D." For myself, I judge men by their work, not by their titles, and regard all properly educated medical men alike as physicians, whatever mode of practice they prefer to pursue.

I am, Sir, &c.,

Z.

MEDICAL NEWS.

THE HOSPITALS' ASSOCIATION.

A PUBLIC meeting, to inaugurate this new association, was held at the Mansion House, under the presidency of the Lord Mayor, on Friday, February 1st. But few members of the profession were present, and the lay members of managing hospital committees were not much better represented; so far, Guy's, St. Bartholomew's, and St. Thomas's Hospitals appear not to have joined in the scheme at all.

The LORD MAYOR cordially welcomed those present to the Mansion House; everything, he said, connected with our great hospitals and their management interested him, he thought that subsequent speakers would give good reasons why such an association as the one proposed should exist, and he wished the movement every success.

Major Ross, M.P. (Middlesex Hospital), on behalf of the provisional committee, stated that the proposed association was the outcome of some previous meetings of those intimately connected with the management of some of the metropolitan and provincial hospitals, and of much promised outside sympathy. He regretted to say that the authorities of the three large endowed hospitals (Guy's, St. Bartholomew's, and St. Thomas's) had not yet joined them, but he hoped after this meeting, and when the objects in view had been established, that they would be prevailed upon to do so. Such an association, he said, among other ways, could be of service by watching Bills through Parliament, and preventing the introduction of clauses which might act vexatiously on the boards of management, and he instanced such a Bill which was introduced in the House of Lords three or four years ago, by which the members of a board would have become personally responsible for the expenditure of the hospital funds. He could not but think that gentlemen who gave their time to the hospitals ought not to be saddled with such responsibility. The association might advantageously discuss all questions involved in hospital management, such as the relation of the out-patient to the in-patient department, the financial management of hospitals, the question of payment by patients or free attendance; the relative diets of different hospitals would also form a suitable subject for their consideration. It was further proposed to form a library of works bearing on the construction, ventilation, and drainage of hospitals; new inventions might be sent for inspection and report. Foreign hospitals would, he thought, in time join with them, and thus a large and varied experience would soon be accumulated.

Sir T. F. BUXTON moved the first resolution: "That in the opinion of this meeting it is desirable to establish, under the name of the Hospitals' Association, and on the basis of the constitution prepared and adopted by the provisional committee, an organisation for the consideration and discussion of matters connected with hospital management." He said it was generally felt that some central association should be formed, by which some of the more pressing questions concerning hospitals might be authoritatively discussed; it was desirable that some sort of concert should exist between hospitals as to the terms on which both in and out-patients were admitted. He thought, for the purpose of encouraging habits of thrift among the working classes, that the provident dispensary system should be more widely diffused than at present, but all gratuitous advice and supplies of medicine given by the hospitals at present tended to thwart this movement. The very unequal distribution of the hospitals in London was another and important question, which could only be adequately dealt with by such a representative association as this one. At present not less than ten of all the hospitals lay within one mile and a-half from Charing Cross, while the outlying districts were practically without any. He hoped also that by united effort they might at last succeed in getting a Royal Commission appointed to consider the whole question. He hoped that many would join as members, even if they did not agree with the recommendations put forth.

Sir RUTHERFORD ALCOCK seconded the motion. He said there could be little difference of opinion as to the need of a better system of management than that which at present prevailed. There was now waste of energy, of money, and of time; none, except the great endowed hospitals, being able to pay their way. Those hospitals which had capital were slowly eating it up, and the remainder were in a state of insolvency, spending each year more than they received. The hospitals were made use of by those who could well afford to pay, and it would be well to establish some means to prevent this. He hoped Government might one day be induced to grant a Royal Commission to inquire into all these points.

Mr. TIMOTHY HOLMES rose to support the resolution, and he did so in order to shew that this movement had the sympathy of medical men as well as of laymen associated with hospitals. Of course he did not in any way wish to appear as the representative of his professional brethren, though he was sure that many of them were in favour of the scheme. As regards the appointment of a Royal Commission, if it should prove instrumental in acquainting the public with every detail of hospital management, it would do great good, and these institutions would be even still better supported by the public than at present. He did not approve, however, of any legislative body (such as had been referred to by previous speakers) which should have control over the hospitals, believing that their present mode of government was far preferable. He thought that a payment system, in some form, should be introduced universally. It was not a little curious that at present only two of the richest hospitals exacted payment; doubtless they had good reasons for doing so. Provident dispensaries had not answered particularly well so far; nor was it to be expected so long as people could get advice and medicine gratuitously at the hospitals. He regretted that the workhouse infirmaries, erected under Gathorne Hardy's Act, were not utilised for purposes of instruction; however important the treatment of disease among the poor was, instruction of medical men was not of less importance. The making available of these institutions for purposes of instruction was one to which the association would have to devote itself.

Mr. HILL made some observations more or less relevant to the motion, which the meeting received with signs of disapproval.

Earl STANHOPE (who now occupied the chair, the Lord Mayor having been called away) was about to put the motion to the meeting, when—

Mr. NELSON HARDY rose to object to the title of the association. He thought its functions should be more defined, and its name should indicate what its functions were. He proposed the "Hospitals' Reform Association." Then, as regards membership, the articles of the proposed constitution said that they should "consist of gentlemen *connected* with hospital administration"—would it not be better to say *interested* in?

Mr. Alderman STAPLES thought that a definite statement of the objects in view should be made by the chairman. He thought we had much better keep the hospitals and their administration in our own hands. A Royal Commission once obtained could not be limited in their enquiry, and they might suggest measures which would be very unwelcome. As to the functions of the new association, it would be very unfortunate if they introduced dissension among hospital committees, and if the idea of mismanagement was spread abroad great harm might result.

Dr. GLOVER asked whether a case had been made out for the establishment of another association. There were already the Council of the Mansion House Sunday Fund, who imposed certain conditions as regards management on all institutions who participated in their awards; and the Charity Organisation Society, which took cognisance of any very obvious imposition on the part of hospital patients. The essential feature of the association appeared to him to be one of criticism, and this he deprecated. The numbers of those who attended the hospitals every year were fallacious; the figures represented visits, and not individuals. What hospitals wanted was cash, and not criticism.

Mr. BOUSFIELD objected to Mr. Hardy's suggestion. The association was not for purposes of reform. He objected to all and sundry being admitted members of the association: only those who were connected with a hospital ought to be admitted.

Earl Stanhope (from the chair) proposed the second resolution: "That the preliminary arrangements connected with the establishment of the Council be entrusted to the Provisional Committee." One of the most important questions to be settled was whether out-patients should be made to pay. He found that each patient at the London Hospital cost 3*s.* 3*d.*, while at the Metropolitan Free the cost was only 9*d.* This could doubtless be accounted for by the nature of the case and its requirements, but the results of an inquiry could nevertheless only prove beneficial. He approved of the payment system, and regretted that there were not more provident dispensaries; he was himself connected with one which worked very successfully. He deprecated state interference with the hospitals; they would be worked more economically and more satisfactorily on their present plan than by the state.

Dr. Farquharson, M.P., seconded the resolution, and expressed himself in favour of the association.

After a vote of thanks to the chairman, the meeting broke up.

British Medical Service.—The following is a list of surgeons on probation in the medical department of the British Army who were successful at both the London and the recent Netley Examinations. The marks shown are those which were gained at the London examination; the order of position of these gentlemen is not affected by the marks gained at the Netley examination:—(1) O. G. D. Bradshaw, 2,410 (gained the Martin Memorial Gold Medal); (2) M. Kelley, 2,375; (3) H. H. Pinching, 2,335 (gained the Parkes Memorial Bronze Medal); (4) R. J. Geddes, 2,350; (5) W. Kelly, 2,185; (6) D. V. O'Connel, 2,170; (7) A. Dodd, 2,140; (8) G. Wilson, 2,121 (gained the Montefiore second prize); (9) J. M. Reid, 1,105; (10) T. B. Winter, 2,105; (11) F. S. Heuston, 2,100; (12) R. J. A. Durant, 2,055; (13) G. F. Gubbin, 2,030; (14) J. P. Myles, 1,980; (15) R. Lesly, 1,975; (16) H. P. Birch, 1,975; (17) M. O'D. Braddell, 1,880; (18) J. J. C. Donnet, 1,870; (19) H. M. Sloggett, 1,845; (20) C. S. Robinson, 1,755.

Indian Medical Service.—The following surgeons on probation in Her Majesty's Indian Medial Service were successful at both the London and Netley Examinations. The final positions of these gentlemen are determined by the marks gained in London added to those gained at Netley, and the combined numbers are accordingly shown in the list which follows:—February 4th, 1884—(1) J. J. Pratt, 5,284 (gained the Herbert Prize of 20*l.* with the Montefiore Medal and prize of twenty guineas); (2) R. Shore, 4,870; (3) W. B. Bannerman, 4,705; (4) C. J. Sarkies, 4,696; (5) H. Thomson, 4,450.

Hospital with Circular Wards.—For some time past an attempt has been made to raise the funds needed to provide hospital accommodation for the town and district of Burnley, Lancashire. The population exceeds 100,000 persons. In addition to the sum of 1,500*l.* as the nucleus of an endowment fund, the committee have succeeded in obtaining subscriptions to the Building Fund to the extent of 12,600*l.*, and a site of two acres in extent has been generously given along with a handsome subscription of 1,000*l.*, by the executors of Colonel Hargreaves. Of the Building Fund over 3,000*l.* have been paid in by the working classes, within a period of nine months, the result of systematic collections at the mills and workshops every four weeks. These collections the committee have suspended for the present, owing to the disturbed state of the cotton trade throughout the whole district, but they hope to be able to resume them ere long. The plans approved of by the committee provide for the erection of a hospital with one-storey pavilion wards of the circular form, as suggested by Professor Marshall, Presidsnt of the Royal College of Surgeons. Two of these wards are to be built at present, with an internal diameter of sixty feet, for the accommodation of twenty beds each. The architects, Messrs. W. Waddington and Son, of Burnley and Manchester, have designed a sun-room or dog-room, on the top of each ward, with a promenade twelve feet wide all round it. Access to the roof is given by a gently sloping spiral staircase, surrounding the smoke and extraction flues, and occupying a closed-in space in the centre of the ward, sixteen feet in diameter. There is thus left for the ward itself, an annular space 22 feet in width. The height of the ward at the eaves is fifteen feet, and at the inner portion sixteen feet. The roof is formed of concrete supported on iron girders. The lineal wall space of the ward is 189 feet, giving an average wall space per bed, excluding doors of about eight feet four inches. The floor space is 132 square feet, and the cubic space 1,560 cubic feet per bed. Windows are placed between each bed, extending from two feet and a half from the floor, to within about a foot of the ceiling; and ample provision is made for ventilation, both at the floor level, and at a height of about seven feet. From the inner part of the ceiling, and also from the floor, ventilating outlets are led to an extraction shaft which encircles the smoke flues. The walls of all the wards, water-closets, and bath-rooms, are to be of glazed bricks or tiles—the floors of the wards are of oak, to be bees-waxed and polished. Separated from each ward by a cross-ventilated corridor, are the bath-room and water-closets. Connecting the circular ward with the main corridor is a well-ventilated passage, on either side of which is a single-bedded, separation ward; and between these wards and the circular ward are the nurse's room and ward scullery. A subway is provided from the cellar floor of the administration block to the wards; in this all pipes will be laid, and along it coal, foul linen, cinders, and sweepings may be conveyed. Provision is made on the site for the addition of four other wards, similar in size to those described, and also for a children's ward for fourteen beds. This is intended to be 40 feet in diameter, to have no central staircase, a sun-room, and to have a dome-shaped ceiling.

The Parkes Museum.—Captain Douglas Galton, C.B., F.R.S., presided at the opening of the spring session at the Parkes Museum, on Thursday, January 31st, when Mr. H. A. Darbishire, F.R.I.B.A., read a paper on "Artisans' and Labourers' Dwellings," in which he described in detail the blocks of dwellings erected by the Peabody trustees which, he urged, were admirably suited to the requirements of the industrial classes who desired to reside in the centre of London or other large towns. Sir Curtis M. Lamson, one of the Peabody trustees, speaking in the discussion which followed, instanced the rent-roll of the Peabody buildings, as showing that they were meeting the requirements of a large section of the labouring classes of London, who alone were admitted as tenants. The annual report for last year showed that the rents amounted to no less than 1,000*l.* a week, or 52,000*l.* a year. Sir Curtis referred to the large areas in the centre of the metropolis which were covered with miserable two-storey dwellings, and he said that, in his opinion, it ought to be illegal to erect these small houses in the centre of London. The trustees did not pretend to house the very poor, and he felt sure this would not be done properly without the intervention of Government. Mr. Mark H. Judge said, that while admitting that buildings on the Peabody plan had done much to improve the condition of the workers of London, he was persuaded that the solution of the overcrowding difficulty would not be reached until the workmen were able to follow their employers by migrating to the suburbs. One of the most needed reforms was frequent and cheap means of transit between the suburbs and the centre of the metropolis. The Artisans' Dwellings Company had demonstrated the soundness of this conclusion. The company was now the largest owner of cottage dwellings in the world, its rent-roll being upwards of 1,500*l.* a week, or half as much again as that of the Peabody trustess. The Artisans' Company, however, could not claim to have reached the very poor, for large as the rent-roll was, the loss by arrears of rent in 1883 was under 200*l.* As to Government interference, Mr. Judge maintained that the local affairs of London were no more the concern of the Legislature than were the local affairs of Liverpool. London was suffering from want of proper local government, and all who wished to see the dwellings of the poor improved might be hopeful of the immediate future with the long-promised Municipal Reform Bill practically in sight. Mr. Judge, in conclusion, said that it was of the utmost importance that reliable data should be forthcoming at the present time, seeing that the earnest attention of the public had been aroused, and he proposed

the following resolution, viz.:—"That the Council of the Parkes Museum be requested to appoint a special committee of medical men, architects, and engineers to enquire into, and report on, the condition of the dwellings of the poor." Mr. H. Rutherford, member of the Council of the Sanitary Assurance Association, seconded the resolution, which was passed, after some further discussion, in which Dr. G. V. Poore, Vice-Chairman of the Museum, referred to the overcrowding existing among the residents of Soho, where the dwellings of the wealthy of a century ago were now occupied by the poor. A vote of thanks was given to Mr. Darbishire for his valuable paper. The next lecture will be on February 12th, when Mr. J. P. Seddon, F.R.I.B.A., will read a paper on "The Ventilation of Theatres."

Gresham Lectures.—Dr. Symes Thompson has announced a course of lectures, at Gresham College, on the International Health Exhibition of 1884, and has issued the following syllabus. Lecture I.—Tuesday, February 12th, 1884. Health Exhibitions.—The aim and scope of health exhibitions; importance of bringing home to the masses of the population precise and definite knowledge of the best means for maintaining health under varying conditions. Better housing of the poor to be attained by better education of landlord and tenant. Widespread ignorance of the first principles of health preservation, and disease distribution; to gain full benefit from the forthcoming exhibition, it is needful to take note of certain primary matters; directions and suggestions derived from a visit to the Berlin Hygienic Exhibition of 1883; various departments, dress, fabrics, and manufactures; food in various countries; drinks of various countries. Lecture II.—Wednesday, February 13th, 1884. On Health in the Home.—How to secure pure air; ventilation; the admission and withdrawal of air; value of open windows and open fires, and of open spaces in large towns; water supply; the "constant system;" drainage, improved methods of construction and arrangement; furniture should not generate dust, or carpets retain it; curtains and vallances; bedding in different countries; non-inflammable felt; hygienic dresses; the school-room, desks, seats; printing of school books; books for the blind; desks for the deaf; the effects on the health from use of gas-light, electric-light, oil-lamps, and candles. Lecture III.—Thursday, February 14th, 1884. Health on the Battle Field.—Transport of sick and wounded; modes of removing a wounded comrade when under fire; hand ambulances; horse ambulances; transport wagons; padded room on wheels for the conveyance of the insane to asylum; hospital trains, arrangement of trucks for officers and for privates; the dispensary; the operating room; the kitchen; hospital tents for field of battle; primary amputations, why more dangerous than amputations for disease in hospitals; Florence Nightingale and her work. Lecture IV.—Friday, February 15th, 1884. Health Restoration in Hospital and Sick Room.—Modern improvements in hospital construction; the "cubic space" and "floor space" necessary for health; the supply and extraction of air; the heating and cooling of wards; the polishing of floors, the use of Parian walls; evils of dust; propagation of germs of disease by dust; microscopic appearances of minute organisms associated with the distribution of certain specific diseases, *e.g.*, yellow fever, cholera, pneumonia, consumption; antiseptics and disinfectants for various purposes for use on a large and small scale; power of cold dry air in destroying infection and consequent fever. The lectures are illustrated by diagrams (lime-light), are free to the public, and commence each evening at six o'clock.

Royal College of Surgeons.—Professor Parker, F.R.S., commenced his course of nine lectures on "Mammalian Descent," in the theatre of the College, on Monday last. The following is his programme, viz.: Lecture I, February 4—Introductory. Lecture II, February 6—On Monotremes. Lecture III, February 8—On Marsupials. Lecture IV, February 11—On Edentates. Lecture V, February 13—On Insectivores. Lecture VI, February 15—On Insectivores (*continued*). Lecture VII, February 18—On Insectivores (*concluded*). Lecture VIII, February 20—On the remaining Orders of the Mammalia. Lecture IX, February 22—On Man, conclusion.

Manchester Children's Hospital.—The medical report for the year 1883, showed that 7,602 new out-patients had been admitted during this year, being an increase of 687 over the numbers of 1882. Of this number 804 were made home-patients, and 230 had died. There were 45,026 attendances, and 2,456 visits to the patients' homes. The cost of each patient was 1*s.* 11½*d.* each. Of 230 deaths, nearly 89 per cent. occurred in children under two years of age. Among other matters of interest, it was noted that the number of cases of chorea applying were on the increase. Thus, in 1871 there were 40 cases of chorea out of 9,101 patients; in 1872, 39 out of 7,957; in 1873, 56 out of 8,227; in 1881, 55 out of 5,773; in 1882, 66 out of 6,916; in 1883, 80 out of 7,602. The question necessarily presented itself, was this increase of chorea due to overpressure at school? Some cases certainly had been produced, or relapses had taken place, during the hard work and mental strain of preparing for examinations. In the hospital at Pendlebury, 1,229 had been under treatment during the year, of which number 1,108 had been discharged, including 117 who had died; 43,001 days had been spent in hospital at 3*s.* 0¾*d.* per day. The average time spent in hospital by the 1,108 discharged was 38·8 days, at a cost of 5*l.* 17*s.* 8¼*d.* per patient. The number of beds, occupied daily, was 117·81. The mortality 10·5 per cent.; 131 more cases had been treated than in 1882, and more than in any other year in the history of the institution. Two hundred and fifteen cases of scarlet fever had been discharged, including 35 deaths, making a mortality of 16·7. The mortality from scarlet fever had been high in consequence of the severe type of disease received. Details of the principal cases treated will appear in the "Abstracts," to be published shortly. The report concluded with a reference to the great loss sustained by the death of the consulting physician, Dr. Borchardt.

Dublin Branch of the British Medical Association.—The seventh annual meeting of this flourishing body was held in the Statue Hall of the King and Queen's College of Physicians, on the 31st ultimo, Dr. Banks presided, and there was a large attendance. Dr. George F. Duffey read the annual report, which detailed the work done by the Branch during the past year. Reference was made to the resolution passed last year at the time when the Medical Act Amendment Bill was passing through the House of Lords, in which the report also referred to recent deputations of the Branch to the Chief Secretary of the Lord Lieutenant, on the subject of Notification of Infectious Diseases, and in support of the Union Officers' Superannuation Bill. It was announced that the Hon. Secretary, Dr. George F. Duffey, did not seek re-election this year as branch secretary, in consequence of the increasing demand upon his time; and the Council had nominated, as his successor, Dr. Richard Haynes, which was carried, after some discussion. On the motion of Dr. Jacob, seconded by Dr. Edward Hamilton, it was resolved—"That this Branch observes with regret the great blank that at present exists in the senior ranks of the Army Medical Department, and the extremely short period of home service now enjoyed by surgeons-major; and they request the Council of this Branch to take such steps as they may deem advisable, to attract the attention of the Government to these points." After the election of officers, the incoming President, Dr. Edward Hamilton, delivered an inaugural address. In the evening the members of the Branch and several distinguished guests dined together.

Dublin Branch of the British Medical Association.—The following have been elected officers. for the year 1884:—President—Edward Hamilton, MD. President Elect—Lombe Atthill, M.D. Vice-Pre idents—E. H. Bennett, M.D; T. W. Grimshaw, M.D. Council—J. K. Barton, M.D.; John T. Banks, M.D.; J. H. Chapman, F.K.Q.C.P.I.; A. H. Corley, M.D.; Geo. F. Duffey, M.D.; Samuel Gordon, M.D.; J. B. Hamilton, M.D., Surgeon-Major A.M.D.; Robert M'Donnell, M.D., F.R.S.; E. D. Mapother, M.D.; J. W. Moore, M.D.; Wm. Moroe, M.D., President K.Q.C.P.; Walter G. Smith, M.D. Representative on the Council of the Association—George F. Duffey, M.D. Hon. Sec. and Treasurer—Richard A. Hayes, M.D., 56, Merrion-square.

Manchester Medico-Ethical Association. — The annual meeting of this association was held on January 31st, 1884. The report of the committee showed the continued prosperity, with a steady increase of members and funds. The following gentlemen were elected office-bearers and members of committee for the year 1884:—President—D. Lloyd Roberts, M.D.; Vice-Presidents—G. Bowring, Esq.; C. J. Cullingworth, M.D.; F. H. Walmsley, Esq.; S. Woodcock, M.D.; Treasurer—Joseph Stone, M.D.; Secretaries—A. Wahltuch, M.D.; J. Broadbent, Esq.; Committee—H. Ashby, M.D.; W. H. Barlow, M.D.; S. Buckley, M.B.; F. H. Collins, M.D.; A. M. Edge, M.D.; J. Foster, Esq.; C. E. Glascott, M.D.; W. J. Mallett, M.D.; E. Meacham, Esq.; F. M. Pierce, M.D.; W. Walter, M.D.; J. Westmorland, Esq.

The Army Medical School at Netley.—The winter session of the Army Medical School was brought to a close, when the prizes were distributed to the successful students, on Monday, by Prince Edward of Saxe-Weimar. Before distributing the prizes, Prince Edward sketched the course of study laid down for the students in the Army Medical School and its advantages, remarking that great thanks were due to the several professors, especially to Surgeon-General Longmore, who had occupied a most distinguished position from the beginning. Director-General Dr. Crawfurd, also addressed a few words to the medical pupils, and said that as there was no special prize for pathology, he had great pleasure in following the example of Sir Joseph Fayrer by giving a copy of Quain's Dictionary of Medicine to Mr. Bradshaw, who stood highest on the list.

Sudden Death of a Medical Practitioner.—Dr. Robert Beales, of Congleton, a magistrate for that borough, and also for the county of Chester, died suddenly on Sunday, immediately after returning from visiting his patients. He was an alderman of the borough, and had been three times mayor.

The Swiney Prize.—The joint committee of the Royal College of Physicians and the Society of Arts have recommended that the award of the goblet and coin, in conformity with the provision of the late Dr. Swiney, be made in favour of Professor Sheldon Amos, M.A., author of a work entitled "A Systematic View of the Science of Jurisprudence." This prize, which consists of a goblet, value 100*l.*, containing gold coin to the same amount, is presented every fifth anniversary of Dr. Swiney's death, to the author of the best published work on medical jurisprudence during the preceding five years, and is given alternately to an exponent of the subject from a medical and from a legal standpoint.

The Grocers' Company and Sanitary Research.—The Grocers' Company have advertised the particulars of their scheme for encouragement of original research in sanitary science. They offer for competition three research scholarships, each of the value of 250*l.* per annum, tenable for one year with eligibility for re-appointment. They intend to appoint to two of these scholarships in May next, and persons who may wish to offer themselves as candidates, are invited to make their applications not later than the last day of April. The scholarships are open only to British subjects under the age of 35. Under the same scheme, and with the same object in view, the Grocers' Company have offered for competition, once in every four years, a discovery prize of the value of 1,000*l.* The prize is to be open to universal competition, British and Foreign. The subject for the first award, for which essays are to be sent in on or before the 31st day of December, 1886, is the following problem:—"To discover a method by which the vaccine contagium may be cultivated apart from the animal body in some medium or media not otherwise zymotic:—The method to be such that the contagium may by means of it be multiplied to an indefinite extent in successive generations, and that the product after any number of such generations shall (so far as can within the time be tested) prove itself of identical potency with standard vaccine lymph." The court, as already stated, will be advised by Mr. Simon, Prof. Tyndall, and Dr. Buchanan.

Canadian Doctors in Parliament.—On the resignation of Mr. Mousseau, the Lieutenant-Governor of the Province of Quebec, Dr. Robitaille, called upon the Hon. Dr. Ross to form a new ministry. Dr. McMillan, of Alexandria, O. has been gazetted a senator of the dominion. There are now over sixty members of the profession in the dominion and local houses in Canada.

Royal Institution of Great Britain. — At the General Monthly Meeting, held on Monday, the Duke of Northumberland, LL.D., D.C.L., President, in the Chair, the Earl Percy, M.P., the Lord Sudeley, the Rev. Edward Samuel Dewick, M.A., F.G.S., Mrs. Charles Hawksley, Sidney George Holland, Esq., LL.B., William S. Playfair, M.D., F.R.C.P., Augustine Robinson, Esq., James Thorne, Esq., and Robert Younger, Esq., B.A., were elected Members of the Royal Institution. Sixteen Candidates for Membership were proposed for election. Sir Joseph Hooker, K.C.S.I., C.B., F.R.S., &c., was elected a Manager in the room of the late Sir William Siemens, F.R.S.

Dublin Hospital Sunday Fund.—The annual meeting of the supporters of this fund took place on Wednesday, January 30. Dr. Grimshaw, Registrar-General for Ireland, read the annual report, in which it was stated that the fund was founded in January, 1874, and the first collection was made on Sunday, the 15th of the following November. Collections were made in 149 places of worship, and a sum of 3,306*l.* 3*s.* 2*d.* was contributed. The area has since then been gradually extended, and the increased support awarded to the fund will be seen by the following statement, which sets forth the number of collections and the amount contributed in each year:—1874, 149, 3,306*l.*; 1875, 195, 3,619*l.*; 1876, 213, 3,873*l.*; 1877, 234, 4,106*l.*; 1878, 230, 4,300*l.*; 1879, 232, 4,329*l.*; 1880, 229, 4,050*l.*; 1881, 232, 4,066*l.*; 1882, 232, 4,193*l.*; 1883, 245, 4,212*l.*—40,060*l.* Thus, a sum averaging about 4,000*l.* a year has been added to the incomes of the sixteen hospitals participating in the fund, thirteen of which were in full work before the institution of Hospital Sunday in Dublin. These satisfactory results naturally afforded ground for congratulation at the meeting. A proposition, that the Council should be instructed to make such arrangements, so as to allocate to the clergy who contribute to the fund, a number of tickets proportionate to what they considered the needs of the parish or congregation, was withdrawn after considerable discussion.

Royal College of Physicians of London.—The following candidates were admitted Licentiates, on January 31, 1884:—

Appleford, Stephen Herbert, 16, Finsbury Circus, E.C.
Armitage, Edward Harris, 23, Brook Street, W.
Beebe, Charles, Edward, 84, Cambridge Street, S.W.
Blaxland, Walter, 126, Victoria Park Road, E.
Blower, Bernard, 119, Shaw Street, Liverpool.
Branthwaite, Robert Welsh, Infirmary, Macclesfield.
Brown, Edwin Harold, Northampton.
Burroughs, Leopold, Manor Villa, Lee, S.E.
Chadwick, James Morley, Heywood, Manchester.
Croft, Edward Octavius, 46, Mornington Road, N.W.
Cummings, Harold Lytton, Dulwich, S.E.
Dowsing, Herbert Leopold, Hull.
Dyer, Sydney Reginald, County Hospital, Huntingdon.
Edwards, William Lloyd, 47, Spurstowe Road, E.
Gooding, Matthew Richard, 67, Oakley Square, N.W.
Graham, George Herbert, Thicket Road, S.E.
Graham, William, M.B. Toronto, 86, Fleet Street, E.C.
Green, Edwin Collier, 3, Telfourd Avenue, S.W.
Harris, John William, 11, St. Thomas Terrace, S.E.
Hart, Arthur Herbert, Edgbaston, Birmingham.
Hingston, Richard, Liskeard, Cornwall.
Hubbard, Frederick Edmund, Kent Hospital, Canterbury.
Hudson, Charles Leopold, Middlesex Hospital, W.
Julyan, Francis Hervey, 14, All Saints Road, W.
Knowles, Henry, Chapel Allerton, Leeds.
Littlewood, Harry, 22, Rutland Street, N.W.
Loring, Jonathan Brown, M.D. Montreal, 58, Doughty Street, W.C.
McConochie, Samuel Watson, M.B. Toronto, 75, Bancroft Road, E.
McDonnell, William Campbell, Park House, Stoke Newington, N.
Maitland, Alfred Derwent, 10, Chester Place, W.
Manders, Neville, Marlborough.
Maurice, William James, Ipswich.
Mills, Robert, Middlesex Hospital, W.
Minns, Allan Glaisyer, Thetford.
Muirhead, Michael Alexander, 33, Trinity Square, S.E.
Neale, John Headley, Highfields, Leicester.
Nuttall, Charles Dalley, 48, Bernard Street, W.C.
Orchard, Alfred, Ashby-de-la-Zouch.
Parry, Herbert Lloyd, 24, Canonbury Park North, N.
Reid, George More, Sydney, New South Wales.
Ross, Elsie Fairfax, 11, Duke Street, Portland Place, W.
Rowland, John Jones, Aberystwith.

Scutt, Tom, Bere Regis.
Sharples, William Henry, Castleton, Manchester.
Sharpley, Edward, Louth.
Sheldrake, Edwin Nodin, 28, Albion Street, W.
Simoens, Joseph Auspicio, 24, Woburn Place, W.C.
Spong, William, Chelsham Road, S.W.
Starr, William Henderson, 8, Roseford Terrace, W.
Sutton, Henry Martyn, 59, Lambeth Palace Road, S.E.
Thompson, Charles Herbert, 85, Lambeth Palace Road, S.E.
Tilley, William James, 28, Shepherd's Bush Green, W.
Tomson, Walter Bolton, St. Thomas's Hospital, S.E.
Trevor, Edward Tull, 48, Queen's Gardens, W.
Trott, Dudley Cox, Caius College, Cambridge.
Udale, Joseph James, 112, Uxbridge Road, W.
Walton, Francis Fielder, Hull.
Weller, Charles Joseph, 67, Coleshill Street, S.W.
White, Ernest Alfred, 13, Blenheim Terrace, Leeds.
Williams, Montagu William, North Eastern Hospital, Hackney Road, E.
Withers, John Sheldon, St. Mary's Hospital, Manchester.
Woods, Edward Robinson, M.B. Toronto, 75, Bancroft Road, E.

The following candidates were admitted members, on January 31, 1884:—

Acland, Theodore Dyke, M.D. Oxford, 79, Lambeth Palace Road, S.E.
Barrs, Alfred George, M.D. Edinburgh, Leeds.
Beatson, William Burns, M.D. St. Andrew's, Bath.
Branfoot, Henry Seymour, M.B. London, Brighton.
Buxton, Dudley Wilmot, M.D. London, 99, Gower Street, W.C.
Campbell, Harry, M.B. London, 40, Keppel Street, W.C.
Herbert, Charles Alfred, L.R.C.P., Westminster Hospital, S.W.
Smith, Robert Percy, M.D. London, St. Thomas's Hospital, S.E.

APOTHECARIES' HALL.—The following gentlemen passed their examination in the Science and Practice of Medicine, and received Certificates to Practise, on Thursday, January 31 :—

Barton, Henry Thos., Bonner Road, Victoria Park, E.
Carr, Thomas, Melbourne Square, Brixton, S.W.
Druitt, Arthur Barthold, Lambeth Road, S.E.
Freeland, Ernest Harding, of the Middlesex Hospital.
Gimblett, Wm. Henry, Devonport Road, Shepherd's Bush.
Hamilton, Henry Thos., Chilham, Kent.
Low, Chas. Wm., Great Plumstead.
Roberts, Geo. Augustus Edwd., Twyford, near Winchester.
Simmons, Harold, Tiverton.
Tatham, Chas. Jno. Willmer, Dollington, Sussex.
Wilkinson, Clement Jno., Gladstone Street, Southwark.
Willan, Leonard Jas., Benthal Road, Stoke Newington.

UNIVERSITY OF CAMBRIDGE.—The undermentioned candidates have kept the Act as required for the degree of Bachelor of Medicine :—

Brinton, R. D., B.A., Downing College, on January 25, 1884.
Crallan, G. E., M.A., Emmanuel College, on January 9, 1884.
Lilley, J. H., B.A., St. John's College, on January 25, 1884.
Salter, S. T., B.A., Emmanuel College, on January 24, 1884.

APPOINTMENTS.

BOOTH, E. H., M.B.—House-Physician to the Seamen's Hospital, Greenwich.
COOMBS, ROWLAND H., M.R.C.S. Eng., L.R.C.P. Lond., L.S.A.—To the Goldington District, Bedford Union.
CROCKER, J. HEDLEY, M.R.C.S., L.S.A.—House-Surgeon to Charing Cross Hospital.
DODSON, A.E., L.R.C.P., L.S.A.—House-Physician to Charing Cross Hospital.
DONALD, JAMES, M,R.C.S. Eng., L.S.A.—To the Kingston District, Kingston-on-Thames parish.
FELIX, E. L., L.S.A.—Resident Obstetric Officer to Charing Cross Hospital.
GROOM, WM., junr., M.R.C.S. Eng., L.S.A.—To the Tenth B District, Wisbech Union.
HUDSON, C. L., L.R.C.P., M.R.C.S., L.S.A.—Resident Physicians' Assistant to the Middlesex Hospital.
HUSSEY, R. L., L.S.A.—House-Physician to Charing Cross Hospital.
JAGO, E. O., M.R.C.S., L.S.A.—Medical Officer for the Cadishead District of the Barton-upon-Irwell Union.
KING, A., M.B., C.M. Ed.—Medical Officer for the Aspley Guise District of the Woburn Union.
LUCAS, A., M.R.C.S., L.S.A.—Medical Officer to the Workhouse, Woburn Union.
M'DONALD, W. B., M.B. Edin.—Medical Officer to the Parochial Board of Drainie, Elgin, N.B.
MACDOWELL, C.W., M.D.T.C.D., F.R.C.S.I.—Medical Officer to the Carlow Workhouse and Fever Hospital.
MOLYNEUX, J. F., M.R.C.S., F.R.C.P.—House-Surgeon to Charing Cross Hospital.
ROBERTS, JOHN F., L.R.C.P. Edin., L.R.C.S. Edin.—To the Ravenstonedale District, East Ward Union.
THOMSON, JOHN, B.M., M.C., M.D. Aber.—To the Dent District, Sedbergh Union.
TOMKINS, ARTHUR WELLESLEY, M.D., L.R.C.S., L.M.—Medical Officer of the Leamington District, of the Warwick Union, *vice* F. Bradley, L.R.C.P. Ed., M.R.C.S., deceased.

DEATHS.

GLEN, JOSEPH, late Physician-General of the Bombay Presidency, at 8, Brook Street, Hanover Square, on Jan. 31, in his 88th year.
HANBURY, INGHAM, Fleet Surgeon, at Bombay, on Jan. 26.
PRINCE, C. E., M.R.C.S., of Buckhurst Hill, Essex, and of Balsham, Cambridge, on Feb. 3.
SMITH, JAMES, M.R.C.S., at Belle Vue Lodge, Richmond, Surrey, on Feb. 2, in his 91st year.
THOMSON, A. T., F.R.C.S., J.P., at Montrose House, Oldham, on Jan. 29, in his 60th year.
TRAVIS, HENRY, M.D., at 20, High Street, Camden Town, on Feb. 4, aged 77.

VACANCIES.

BOSCOMBE PROVIDENT INFIRMARY, BOURNEMOUTH.—Resident Medical Officer. Salary £60 per annum, with board, &c. Candidates must be duly registered and unmarried. They are prohibited from engaging in private practice. Applications, together with copies of testimonials, to be sent to the Secretary, before February 11.
CHESTERFIELD UNION, BOLSOVER DISTRICT.—Medical Officer. Area 9,211 acres. Population 2,758. Salary £21 per annum.
CITY OF ELY DISPENSARY.—Surgeon and Dispenser. (*For particulars see Advertisement.*)
GRANTHAM UNION, GRANTHAM DISTRICT.—Medical Officer. Area 11,877 acres. Population 15,499. Salary £96 per annum.
HANTS COUNTY LUNATIC ASYLUM.—Junior Assistant Medical Officer. Salary £120 a year, with board, lodging, washing, and attendance. Candidates must be duly registered. Applications with copies of recent testimonials, to be sent to Dr. Mauley, on or before February 15.
NOTTINGHAM BOROUGH ASYLUM.—Assistant Medical Officer. Salary £100 a year, with board, apartments, and washing. Candidates must be duly qualified in Medicine and Surgery, and registered. Applications, with testimonials, stating age, &c., to be sent to the Medical Superintendent, on or before February 16.
ROYAL SURREY COUNTY HOSPITAL, GUILDFORD.—House Surgeon. (*For particulars see Advertisement.*)
ROYAL FREE HOSPITAL, GRAY'S INN ROAD.—Senior Resident Medical Officer. (*For particulars see Advertisement.*)
THE HOSPITAL FOR WOMEN, SOHO SQUARE.—Assistant Physician. (*For particulars see Advertisement.*)
THE GENERAL HOSPITAL, BIRMINGHAM.—Resident Medical Officer. (*For particulars see Advertisement.*),
THIRSK UNION, KILBURN DISTRICT.—Medical Officer. Area 2,662 acres. Population 387. Salary £8 per annum.

NOTES, QUERIES, AND REPLIES.

THE HIND FUND.

WE are requested to state that this fund will be closed on Thursday, March 6th next, until which date subscriptions will be thankfully received by Dr. Richardson, P.R.S. (chairman), 25, Manchester Square; John Tweedy, Esq., F.R.C.S., 24, Harley Street, hon. treasurer; A. J. Pepper, Esq., F.R.C.S., 122, Gower Street; and Thomas Wakley, jun., Esq., L.R.C.P., 96, Redcliffe Gardens, hon. secretaries; or by Messrs. Coutts & Co., Strand. The following additional contributions have been received and paid to the account of the "Hind Fund" at Messrs. Coutts' Bank:—Jonathan Hutchinson, Esq. (additional donation), £5 5*s.*; Dr. C. J. Sylvester, £2 2*s.*; James Somer, Esq., £1 1*s.*; Dr. Danford Thomas, £1 1*s.*; T. Rogers, Esq., £1; Dr. Woakes, £1; H. Muscroft, Esq., 10*s.*

THE MEDICAL ACTS AMENDMENT BILL.

TO THE EDITOR OF THE MEDICAL TIMES.

SIR,—I am desirous of occupying a space in your columns with reference to the above contemplated measure, which is likely again to engage the attention of Parliament this Session, in all probability in both Houses, the discussion of its various, almost bewildering, clauses not being, as last year, confined to the Upper Chamber. Permit me to assert at commencing that I believe fully and sincerely in the remarks about to follow, which must be judged of or taken into consideration by your numerous readers, as to whether they are worthy of any attention on their part; for ample thought on the part of the profession has scarcely been sufficiently given or drawn to the radical changes proposed to be effected. When the discussion on the Bill commenced, no little surprise, and, indeed, proper indignation, was felt, and openly expressed, that the Society of Apothecaries was left out in the cold; sinister influence, apparently, had been at work. What had the Society done in the past, or what is it doing at the present, to deserve such an unmerited slight? Let that pass by. The three boards are the great panacea offered in the forthcoming Bill. The licensing bodies—many of them grand institutions in themselves, which have not only devoted their energies towards the teaching and instruction of the medical student for ages past, but have also been the means of keeping up museums and libraries—are to be thrust aside, and "the license in surgery, medicine, and midwifery of the General Medical Council" is to be the open sesame to the "Medical Register." Will the high-sounding title be cared for? All associations revered in themselves, and handed down from generation to generation, are to be ignored, for it is not to be supposed that students will choose to pay extra fees and undergo supernumerary examinations, such as that for the F.R.C.S., &c.—the admission to the portals of the profession being already so very heavy, as parents know to their cost. The General Medical Council, out of their enormous procreative funds, have for some years past devoted a sum worthily to "Visitations of Examinations." Reports extending over a lengthened period lie

before me. What do I find? That the licensing bodies have right loyally, truthfully, and honestly carried out the behests and requirements of the Council, whilst the highest educational standard has been attained that can well and in all justice be anticipated. There is a restless spirit permeating or spreading over the present age, a morbid desire for change, without caring or looking out for ulterior consequences, but I would ask members of the profession in the three divisions of the United Kingdom to rally round and close their ranks against a measure so pernicious, insidious, and destructive as the contemplated Government Medical Acts Amendment Bill.

I am, Sir, &c.,
A CONSTANT READER.

C. C. Dickson.—Your request shall be attended to.

D. A. Patvarohan, Esq., Jamkhandi, India.—Postcard and remittance received, with thanks.

L. S. A.—To become a member of the Apothecaries' Society, one must serve an apprenticeship to a member. There is a yearly payment of Ten Shillings quarterage, towards the expenses of the Chelsea garden; but this, we hear, will shortly be abolished "Constant Reader," see *Le Progrès Médical*, 1883, No. 47.

M. R. C. S.—The Director-General of the Army Medical Department is the only person who could cause you to be furnished with the papers you require. Formerly they were published in the Annual Blue-Book, but this practice has been discontinued for some time. We have heard a rumour that it is not unlikely they may shortly be made public, after each examination, through the medium of the Medical Journals.

Mr H. J. Johnstone.—We have not space to notice this pamphlet this week, but hope to give it our consideration in our next issue.

COMMUNICATIONS RECEIVED—

Sir EDMUND LECHMERE, London; Prof. PAGET, M.D., F.R.S., Cambridge; Dr. WILKS, London; Mr. WM. YOUNG, London; Mr. G. WALPOLE, London; Dr. C. ALLBUTT, Leeds; Dr. W. OSLER, Montreal; Dr. G. COATES, London; THE REGISTRAR, ROYAL COLLEGE OF PHYSICIANS, London; Dr. WAHLSUCH, Manchester; Dr. C. BROWNE, London; Dr. LUDWIG LOEWE, Berlin; THE SECRETARY, APOTHECARIES' HALL, London; THE HON. SECRETARY, MEDICAL SOCIETY OF CHARING CROSS HOSPITAL, London; THE SECRETARY, SOCIETY FOR THE ENCOURAGEMENT OF ART, &C., London; THE DIRECTOR, ANTHROPOLOGICAL INSTITUTE OF GREAT BRITAIN AND IRELAND, London; Dr. J. W. MOORE, Dublin; Dr. ALEXANDER, Liverpool; Mr. H. RAYNER, Newcastle-on-Tyne; THE SECRETARY, ROYAL INSTITUTION, London; Mr. H. H. J. JOHNSTONE, Ramsgate; THE REGISTRAR-GENERAL FOR SCOTLAND, Edinburgh; THE ASSISTANT SECRETARY, ROYAL MICROSCOPICAL SOCIETY, London; Mr. F. H. OLIVER, Maidstone; Mr. G. THOMSON, Oldham; THE SECRETARY, ROYAL COLLEGE OF SURGEONS, London; Mr. STONE, Wimbledon; THE SECRETARY, PARKES MUSEUM, London; Dr. E. S. THOMPSON, London; Mr. C. C. DICKSON, Edinburgh; Mr. JOHN BELLAMY, LOCAL GOVERNMENT BOARD, London; THE SECRETARY, SCHOOL OF MEDCINE, Netley; Mr. J. BROWN, Burnley, Lancashire; THE SECRETARY, ROYAL MEDICAL AND CHIRURGICAL SOCIETY, London.

BOOKS RECEIVED—

Report on the Kensington District, Dec. 29, 1883, to Jan. 26, 1884—Transactions of the American Gynæcological Society for the year 1883—Geographical and Historical Pathology, by Dr. August Hirsch—Diseases of the Liver, by Henry R. Ruckley—Transactions of the American Surgical Association—The Drainage Schemes proposed for Ramsgate, by Henry James Johnstone, J.P., F.R.C.S.—Prodromal Symptoms of Psychical Impairment, by C. H. Hughes, M.D. St. Louis—Chronic Meconism of Papaverism, by C. H. Hughes, M.D. St. Louis—Der Hypnotismus, von Dr. Conrad Rieger—New Forms of Nerve Terminations in Mammalian Skin, by George Hoggan, M.B.—Compend of Anatomy, by J. B. Roberts, Am. M.D.—Inorganic Chemistry, by Prof. Victor von Richter—International Review of Medical and Surgical Technics—The Lockjaw of Infants, by J. F. Cameron.—The Sanitation and Reconstruction of Central London, by William Westgarth.

PERIODICALS AND NEWSPAPERS RECEIVED—

Lancet—British Medical Journal—Medical Press and Circular—Berliner Klinische Wochenschrift — Centralblatt für Chirurgie — Gazette des Hopitaux—Gazette Médicale—Revista de Medicina—Bulletin de l'Académie de Médecine—Pharmaceutical Journal—Wiener Medicinische Wochenschrift — Revue Médicale — Gazette Hebdomadaire — Nature — Boston Medical and Surgical Journal — Louisville Medical News—Centralblatt für Gynäkologie—Le Concours Médical—Centralblatt für die Medicinischen Wissenschaften—Centralblatt für Klinische Medicin—Philadelphia Medical News—Le Progrès Médical — New York Medical Journal — Students' Journal and Hospital Gazette — New York Medical Record—The Edinburgh Clinical and Pathalogical Journal—Edinburgh Medical Journal—The Analyst—An Ephemeric of Materia Medica, &c.—Sheffield and Rotherham Independent—The Ophthalmic Review—The Practitioner—Brain—The Veterinarian—Archives Générales de Médicine—The Monthly Homœopathic Review—Revue Mensuelle de Laryngologie, &c.—National Anti-Compulsory Vaccination Reporter—The Western Daily Mercury—The Glasgow Medical Journal — St. Petursburger Medicinische Wochenschrift — The Sanitary News, Chicago—The Bath Herald—The Australian Gazette—The Medical World—Popular Science News—Canada Medical and Surgical Journal.

APPOINTMENTS FOR THE WEEK.

February 11. *Monday.*

MEDICAL SOCIETY OF LONDON.—Mr. Bryant, "On the Treatment of Irreducible Hernia, and an improved method of adapting a Truss in Hernia generally;" Mr. Jonathan Hutchinson, "On Lupus Disease of the Skin."

ROYAL COLLEGE OF SURGEONS OF ENGLAND, 4 p.m.—Prof. W. K. Parker, F.R.S., will deliver his Fourth Lecture "On Mammalian Descent."

12. *Tuesday.*

ANTHROPOLOGICAL INSTITUTE OF GREAT BRITAIN AND IRELAND, 8 p.m.—The following Communications will be received: (1) J. Park Harrison, Esq., M.A., "Exhibition of Skulls and other Remains from a Cemetery at Wheatley;" (2) G. B. Barron, Esq., M.D., "On a Human Skull found near Southport;" (3) Miss A. W. Buckland, "Traces of Commerce in Prehistoric Times;" (4) John T. Young, Esq., F.G.S., "On some Palæolithic Fishing Implements from the Stoke Newington and Clapton Gravels."

PARKES MUSEUM, 5 p.m.—J. P. Seddon, F.R.I.B.A., will deliver a Lecture "On the Ventilation of Theatres."

ROYAL INSTITUTION, 3 p.m.—Prof. A. Geikie, "Scenery of the British Isles."

ROYAL MEDICAL AND CHIRURGICAL SOCIETY, 8.30.—W. H. Broadbent, M.D., will read a Paper, "On Alcoholic Paralysis;" by the President, a communication from Dr. Straus of Paris, Chief of the French Scientific Commission sent to Egypt to investigate the cholera; Dr. Straus' microscopical preparations will be on view at 8 o'clock.

13. *Wednesday.*

EPIDEMIOLOGICAL SOCIETY OF LONDON, 8 p.m.—Meeting. The evening will be devoted to the discussion of Surgeon-General Hunter's Paper, "On the Origin of the Cholera Epidemic of 1883 in Egypt."

ROYAL COLLEGE OF SURGEONS OF ENGLAND, 4 p.m.—Prof. W. K. Parker, F.R.S., will deliver his Fifth Lecture "On Mammalian Descent."

ROYAL MICROSCOPICAL SOCIETY, 8 p.m.—Annual Meeting.

14. *Thursday.*

ROYAL INSTITUTION, 3 p.m.—Prof. Pauer, "Music for the Pianoforte," &c.

15. *Friday.*

MEDICAL SOCIETY OF CHARING CROSS HOSPITAL, 8 p.m.—Meeting. M. C. F. Clarke, M.R.C.S., &c., will read a Paper "On Skin Diseases in Children."

ROYAL COLLEGE OF SURGEONS OF ENGLAND, 4 p.m.—Prof. W. K. Parker, F.R.S., will deliver his Sixth Lecture "On Mammalian Descent."

ROYAL INSTITUTION, 8 p.m.—Prof. Thorpe, "The Chemical Work of Wöhler."

16. *Saturday.*

ROYAL INSTITUTION, 3 p.m.—Prof. Morley, "Life and Literature under Charles I."

TERMS OF SUBSCRIPTION FROM JANUARY 5, 1884.

BEIJERINCK'S RESEARCHES ON THE GUM-DISEASE IN PLANTS.

Communicated by Sir JAMES PAGET, Bart., F.R.S.

An Essay, by my friend Dr. Beijerinck,[1] on the contagion of the gum-disease in plants, which has lately been published by the Royal Academy of Sciences at Amsterdam, contains so many facts likely to be useful in the study of contagions in animals, that I venture to ask you to insert a brief notice of its chief contents. The gum-disease (gummosis, gum-flux) is only too well known to all who grow peaches, apricots, plums, cherries, or other stone fruits. A similar disease produces gum arabic, gum tragacanth, and probably many resins and gum-resins. It shows itself openly in the exudation of thick and sticky or hard and dry lumps of gum, which cling on branches of any of these trees where they have been cracked or wounded through the bark. To any students of medicine or pathology who live within range of such trees, Dr. Beijerinck's observations may suggest some interesting researches.

Dr. Beijerinck was induced to make experimental inoculations of the gum-disease by suspicions that, like some others observed in plants, it was due to bacteria. He ascertained that it is in a high degree contagious, and can easily be produced by inserting the gum under the edge of a wound through the bark of any of the trees above named. The observation that heated or long-boiled pieces of gum lose their contagious property made it most probable that a living organism was concerned in the contagions; and he then found that only those pieces of the gum conveyed contagion in which, whether with or without bacteria, there were spores of a relatively highly organised fungus, belonging to the class of ascomycetes: and that these spores, inserted by themselves under the bark, produced the same pathological changes as did the pieces of gum.

The fungus, thus detected, was examined by Professor Oudemans, who ascertained it to be a new species of Coryneum, and has named it Coryneum Beijerinckii. Its characters, which are minutely described, are chiefly that it has a cushion-like stroma, consisting of a bright brown parenchyma, on which numerous conidia stand on colourless, unicellular and very slender stems, about as long as themselves. The conidia are small, cask-shaped, about one-thirtieth of a millimetre in length, and usually divided by slightly constricting septa into four cells, of which the two terminal are longer than the two middle. From these cells germinal filaments may proceed, from which are developed either yeast-cells, or brown thick-walled and many-celled mycelia.

The inoculation experiments are best made by means

[1] *Onderzoekingen over de Besmettelijkheid der Gomziekte bij Planten*: door Dr. M. W. Beijerinck. Amsterdam, 1883. 4to.

of incisions through the bark of young branches of healthy peach-trees or cherry-trees, and by slightly raising the cut edge of the bark and putting under it little bits of gum from a diseased tree of the same kind. In nearly every instance these wounds become the seats of acute gum-disease, while similar wounds in the same or other branches of the same tree, into which no gum is inserted, remain healthy, unless, by chance, gum be washed into them during rain. The inoculation fails only when the inserted pieces of gum contain no coryneum.

By similar inoculations similar diseases can be produced in plum, almond, and apricot-trees, and with the gum of any one of these trees any other can be infected; but of many other substances which Beijerinck tried, not one produced any similar disease.

The inoculation with the gum is commonly followed by the death of more or less of the adjacent structures; first of the bark, then of the wood. Small branches or leaf-stalks thus infected in winter, or in many places at the same time, may be completely killed; but, in the more instructive experiments the first symptom of the gum-disease is the appearance of a beautiful red colour around the wound. It comes out in spots like those which often appear spontaneously on the green young branches of peach-trees that have gum-disease; and in these spots it is usual to find coryneum-stromata, or mycelium-filaments. The colour is due to the formation of a red pigment in one or more of the layers of the cells of the bark.

But in its further progress the disease extends beyond the parts at which the coryneum, or any structures derived from it, can be found; and this extension, Beijerinck believes, is due to the production of a fluid, of the nature of a ferment, produced by the coryneum, and penetrating the adjacent structures. This, acting on the cell-walls, the starch-granules, and other constituents of the cells, transforms them into gum, and even changes into gum the coryneum itself, reminding the observer of the self-digestion of a stomach.

In the cells of the cambium, the same fluid penetrating unites with the protoplasm, and so alters it that the cells produced from it form, not good normal wood, but a morbid parenchymatous structure. The cells of this parenchyma, well known among the features of gum-disease, are cubical or polyhedral, thin-walled and rich in protoplasm. This, in its turn, is transformed into gum, such as fills the gum-channels and other cavities found in wood, and sometimes regarded as gum-glands. And from this also the new ferment-fluid constantly produced, and tracking along the tissues of the branches, conveys the coryneum infection beyond the places in which its mycelium can be found.

CLINICAL LECTURES

By J. MATTHEWS DUNCAN, M.D., F.R.S.,
Physician-accoucheur and Lecturer on Midwifery at St. Bartholomew's Hospital.

Lecture VI.

ON CANCER OF THE CERVIX UTERI.

This is the most terrible of the diseases of women, partly because it is one of the most frequently occurring. We see less of it than of other grave diseases in "Martha," proportionally to its commonness, because a large number of the cases that come to us are utterly incurable, and can get no special benefit from hospital treatment; they are either not admitted or soon dismissed.

Sometimes these patients are not great sufferers in respect of pain or uneasiness; sometimes they have great pain. Always their condition is awful: the very name of the disease depresses and paralyses the patient, her friends, and her physician. In every case much can be done by ordinary medical attention — the use of laxatives and of opiates—the management of diet and regimen. Most cases have copious, and often fœtid, watery, ichorous discharge, whose constant flow irritates the vulvar surfaces. Against this many special means have been proposed, and much praised; but all resolves itself into mere cleanliness—a supply of dry linen, copious, so that the cloths may be frequently changed; washing with warm water; syringing with antiseptic lotions. By these means you do not prevent the discharge, you do not, unless momentarily, destroy fœtor, but you maintain comfort, and reduce the fœtor to a minimum. If a vesicovaginal fistula has been established by progressive ulceration and sloughing, and this is common, you have to use the same care as when you have only vaginal discharge; but success in maintaining comfort and cleanliness is much more difficult to attain. Ointment, as of bismuth, or of boracic acid, for the sore skin of the vulva, or of the thighs, is often of use. When there is rectovaginal fistula, which is rare, it is still the same: cleanliness is the great resource.

It is in every case impossible to state the duration of the disease. Most cases have at first no symptoms at all, or so slight, and therefore attracting little attention, that they do not come to us till the disease is far advanced. This is more true of sarcoma than of carcinoma. In diseases ending fatally, one end of the line is clearly defined by death. The beginning, also, is easily made out in many acute diseases, but in this disease we have no way of making sure of the beginning, even if we were constantly examining. It is common to say that hypertrophy and induration, or a real ulcer, not a mere abrasion, or a hardness with big-grained roughness, or a nodule with or without ulcer, or with little ulcers healing and reappearing, is the beginning of the disease, and it may be so; these are, at least, often very early indications, practically the earliest during life; but before these conditions appeared, there may have been malignant degeneration going on. We had a fatal case of cancer of the body of the uterus, sarcoma, involving all its tissues except the peritoneum, and in it the cervix had, before and after death, every appearance of health to the most careful macroscopical enquirer, and it presented the same characters of health to the finger examining per vaginam, yet microscopical investigation showed cancerous degeneration in its tissue. All statements, therefore, of the duration of this disease are to some extent mere guesses, for in most cases we have no grounds for fixing its time of beginning, and the earliest and best grounds attainable are indications of disease already considerably advanced.

Generally the patient or anxious friends press you with the question, "How long will it last?" The answer to this must always be very guarded, for at the best it is very rough; and, besides, intercurrent disease connected with the cancer may at any time and almost suddenly prove fatal, perhaps eighteen months or two years after the disease is distinctly recognised. Some sarcomas last much longer than common cancers. Sometimes, and I think especially in young people, cancer is an acute disease, running its course rapidly. A young lady applied to me on account of slight continued bloody oozing from the vagina: there was nothing unhealthy discoverable, except on the posterior vaginal wall, a wart the size of half a small pea. It was freely destroyed by caustic. The disease rapidly extended, forming large fixed masses around the lower part of the vagina, and she was dead within three months from the discovery of the wart. A patient came into hospital with a little induration of the fossa navicularis, and nothing else discoverable. She was dead in

six weeks, and the pelvis was then well filled by large masses of soft cancer. Sometimes, on the other hand, and especially in old people, the disease is very prolonged. In hard cancers of the mamma, great slowness of progress in old people is not rare. In the uterine cervix you rarely have the hardest kind of cancer, and slow progress is much rarer than in cancer of the mamma. The longest case of uterine cancer that I remember, never presented scirrhous hardness. It began as an ulcer on a soft and slightly hypertrophied cervix in a sterile woman about 48 years of age. Though the ulcer was, from the first, not an abrasion, but distinctly edged, and in appearance somewhat callous, I hoped to be able to make it heal; but my attempts by caustic were vain. She survived the discovery of the ulcer five years.

If you see a case from time to time, and find the cancer rapidly growing and extending, that indicates a speedy progress towards death. This fatal career may be accelerated by hæmorrhages. Generally, the approach of the end is preceded by recognisable morbid conditions—red and beefy tongue more frequently than foul furred tongue, progressive general weakness, progressive loss of flesh. Often the end is heralded by swelling of the lower limbs, generally from venous obstruction—often from a modified subacute phlegmasia dolens. Very rarely you have, from communicated disease of the sacral nerves, peculiar contractions of muscles, or spasms, or persistent mapped pains, in one or other leg, according to the side affected.

When you first see a case of cancer of the neck of the womb, you rarely have any difficulty of diagnosis. There have been recurrences of irregular bleeding or continued oozing of blood, discharge of watery or sanious fluid more or less copious, and frequently horribly fœtid, pain in the back, or just above the groins or down the thighs. But these three great symptoms of the disease may not only be very diversely modified; they may—one, or two, or all—be absent altogether. Cases, indeed, occur not very rarely where there are no striking symptoms even till death: and this circumstance has led to many mistakes in diagnosis. But it is not on symptoms, however severe and well marked, that you finally rely: it is mainly on the physical examination. The finger discovers one or more of the following conditions: induration, nodulation, hypertrophy, outgrowth, excavation, fixation, such as can be attributed only to cancerous growth and extension or cancerous ulceration, sloughing, and decay. It is vain to attempt to describe in words what you find, so various may it be: you will soon learn, and easily, by sad experience. If there is no bleeding, or very little, and if the vagina is not much affected, you may, through the speculum, take a look at the parts, and see a bluish, nodulated, perhaps ulcerated, ulcer perhaps having overhanging edges, portions of dirty yellow slough. I have not words to paint the grievousness of these cases. A woman, still blooming and active and useful, consults you for some trivial matter about her womb: you examine, and find cancer. At once, and unexpectedly, your diagnosis places you in a position demanding the wisest action of head and heart.

A sarcoma may present characters like those of the common cancer of the neck; but, generally, it more or less simulates a fibroid—of the neck or of the body. The uterus is not so early fixed, and constitutional symptoms may be long delayed. If you have occasion to remove any part, the histologist will settle for you whether it is a carcinoma or a sarcoma.

Every case is not easy of diagnosis, and it is necessary to consider these exceptional instances. The difficulty may be great, and the verbal description is no easy matter, so many are the conditions, and so nice the distinctions—degrees of patulousness, or of constriction of os, or of cervical canal, induration, fixation, hypertrophy, warty roughness, nodulation, outgrowth, fissuring, abrasion or erosion, kinds of ulceration, excavation. Of course, if you take plenty of time, and await the increasing ravages of the disease, you can easily reach assurance as to the nature of it. But you must, if possible, diagnose at once, and if not at once, as soon as possible. To say, this is not cancer, is grand comfort to the patient and her friends.

Sometimes a small sessile polypus, or two or three of them, or a group of hard Nabothian follicles give rise to shortlived difficulty. Sometimes great alarm is caused by the bloody and fœtid discharge of a bigger polypus, perhaps just passing through the cervix, and perhaps sloughing at its lowest part. I have seen a sloughing fibroid give rise to bad diagnosis and great alarm, as also an enucleated fibroid rotting in the vagina. In elderly women a bleeding vaginitis or a bleeding endometritis will naturally cause alarm, especially if there is also fœtid discharge.

The most common cause of difficulty and of error is mistaking for cancer a case of chronic inflammation of the cervix with hypertrophy. In such there are sometimes nodulation and deep fissures, and diffused swelling affecting even the vaginal laqueus, and the difficulty of diagnosis may be insuperable at the time. You may, indeed, have a combination of cancerous degeneration and chronic inflammatory hypertrophy. We had, not long ago, in "Martha," an instructive case of this kind. At first we diagnosed cancer, but not with high assurance, and treated for chronic inflammation—milk diet, rest in bed, laxatives, embedding the cervix in ointment of iodide of lead every night. After little more than a week there was so much improvement—diminution of hypertrophy, disappearance of surrounding swelling, resumption of natural colour—that we hoped the case would turn out to be one of mere chronic inflammation and its results. The woman left the hospital, but returned in some months with unmistakeable cancer of the cervix. Suspicious cases, however, do occur where treatment fortunately removes all disease. In these we do not cure cancer; we only remove conditions which were mistaken for those of cancer, or raised grave suspicions of that malignant disease.

We see little of syphilis in "Martha," and I have never seen a case of syphilitic ulceration of the cervix or vaginal roof that could be mistaken for cancer. We have had, and not long ago, a case of chancre of the cervix—two rounded callous ulcers, about a line in diameter, with grey bases, rapidly healed by dusting with calomel, but these ulcers did not suggest cancer. There is, however, syphilitic hypertrophy of the cervix which may be mistaken for cancer, and we have had a grand example in a woman with a syphilitic history and very depressed general health. The cervix was hypertrophied in the form of two very hard semiglobular projections, each nearly as big as a walnut, not ulcerated but abraded on their inner sides. We were disposed to regard the tumours as malignant, yet tried anti-syphilitic treatment, with amputation of the projecting lumps. Nothing but the great improvement, of local and general health, maintained for more than a year, convinced us that the disease was not malignant.

Lupus of the genital organs, or the disease so-called, may be mistaken for cancer. It often is so when it attacks the pudendum and vagina; and the disease is, in these parts, not very rare. In the cervix uteri lupus is very rare, and I have not seen any case that could give rise to mistake. Indeed, our only case in "Martha for the last six years occurred very lately, and it had no resemblance to cancer. The woman had irregular bleedings for fourteen years, and her cervix uteri

*

presented a mapped ulceration that could not be mistaken for abrasion, or erosion, or malignant disease.

Parametric, or perimetric, induration may tend to increase difficulty or confusion in cases of cancer of the cervix; but on this subject I have not time now to enter, especially as I shall take it up some other day.

We have almost always some case of cancer in the wards, and it is not only cases of doubtful diagnosis that we take in for observation and treatment. We may consult a patient's convenience by giving her lodging for a few days: we may during a few days' residence, and, perhaps, by an additional consultation, satisfy the poor sufferer that her case has been well considered: we may, by our examinations, have induced bleeding, which demands plugging and horizontal rest for some time. But the cases we take into the wards are, for the most part, cases in which we hope to do decided good by operation.

I cannot say that we take in cases for extirpation of the disease by operation, hysterectomy. Would that this were the case. Seldom do we see a case such as tempts the sanguine and adventurous. Fixation of the uterus, or felt extension of the disease to the vagina or parametric or parauchenic tissues, renders any hope of extirpation foolish in most cases. Excision of the whole uterus has twice been done in "Martha," death following the operation in a few days. The operation is much more difficult than extirpation of the mamma, and it is, meantime at least, very much more dangerous; and for this reason scarcely to be recommended. In cases of the early stage of cancer of the body of the uterus, with free mobility and healthiness in other respects, the operation has good prospects, for we may hope the disease is closely localised, and may be all removed. It is not so in cancer of the cervix, for it lies in parametric or rather parauchenic tissue into which the disease has probably extended, and that without interfering with softness and mobility, or the indications of health. The parauchenic tissues cannot be so thoroughly examined as the tissues around the mamma.

Attempts to extirpate the disease, otherwise than by excision of the organ, are comparatively mere trifling, and, for my part, I say nothing for them. Partial excisions, scooping out, burning out, repeated numerous operations, are objectionable, do more harm than good. I do not say that all of these words apply to every individual case, for I have felt convinced that attempts at extirpation, attempts even, have done good. Remarkable atrophy, or shrivelling of parts, I have, in two recent cases, observed to accompany complete healing of the wounds made by the operator's caustic; and in one there was remarkable and very extraordinary retardation of progress, disease becoming again urgent only after three years of supposed or apparent good health. If we knew what cases would be so fortunate, we would operate in them; or, if such fortunate cases were frequent, we would operate in every case. But such fortunate cases are single and rare, in a large crowd, and should not govern our practice. Generally the histories of this kind of proceeding are mere lamentable samples of nimia diligentia; the patient would have been happier and healthier if carefully let alone.

In "Martha" we sometimes burn severely or deeply, and repeatedly, cancerous ulcers of the cervix, especially if the disease is not far advanced; and almost invariably it is the actual cautery that we use—Paquelin's. I daresay we sometimes do it, impelled rather by desire to please the patient by a demonstration of activity, than by strong expectation of doing good. We do not deceive either her or ourselves by hope of cure. Whether, on the whole, we do good or not, I am not quite sure. The patient is encouraged. Discharge may be diminished. Rarely, as I have just said, when speaking of cauterising, or scooping out, with a view to extirpation, there is, apparently at least, great benefit. I have seen the ulcer contract and heal completely after repeated cauterisation. But sometimes the operation acts as an irritant, and accelerates progress, or appears to do so. After all, there is probably gain on the whole. Were it not so, we would not practise it. This cauterising is our commonest treatment; and, saying commonest does not imply that it is nearly always resorted to. Far from it; in most cases it is best to do nothing—an impotence most painful to the practitioner. Cases are suitable where the ulcer constitutes the chief part of the disease, is well seen, and can be thoroughly dealt with.

Our chief reason for taking cases of cancer of the neck of the womb into "Martha," is to incise large prominent or outgrowing portions, for in this way we undoubtedly do much good—great gain that is substantial for a time; rarely is the gain not considerable; improvement in both local and general health comes quickly. Sometimes the improvement of the general health is very great, and occasionally marvellous. Encouragement of the patient, restored cheerfulness, arrested discharge, may do much; but in some cases these are not sufficient to explain the marvellous restoration, and I will give you an example from another department of pathology. In this example there was no arrested discharge, no rescue from the fear of cancer. The woman was carried into hospital in a dying state, extremely emaciated, and supposed to have malignant ovarian cystoma. She really had a great hydroperitoneum, and solid sarcoma of both ovaries. The belly was emptied, and immediately improvement began. She soon resumed a comparatively healthy appearance, put on flesh, and walked out of the hospital to resume her occupation at home. A few months afterwards she again became very ill and died. This illustrates the kind of gain we obtain by operation, and it is well worth the suffering and trouble of enduring the process.

Sometimes you have an outgrowth, and presumably nothing more, as in some cases of cauliflower excrescence. Occasionally, indeed, in this kind of tumour, you have an almost polypoid form, the thick stalk springing from a lip of the cervix. This epithelial growth, with its extensive granulated surface, bleeds freely, and discharges copiously a watery irritating fluid. All its conditions invite excision, and the results are the best, sometimes even cure; or, if not cure, failure to return while life lasts; and thus, if not cure in an absolute sense, at least cure for the individual.

But all cases of outgrowth into the vagina have not a line of treatment plainly marked out as in epithelioma, with some kind of neck; and it is desirable to state the conditions which invite operation, and those which forbid it.

First, there must be a large piece removable, it may be of the size of a walnut, or of the size of the fist. Second, there must be a fair proportion between the mass removed and the extent of wound left; it must not be a shaving off of the surface. Then, you are encouraged by the limited character of the disease, perhaps the uterus still is mobile, no masses, or even hardness, can be felt beyond the cervix and its immediate neighbourhood. Further, the more the discharge the greater the impulse to operate, for you expect the wound to contract, or even heal, and to have diminution or arrest of discharge, at least for a time; and it is probably chiefly by diminution of discharge that gain is in most cases obtained.

The operation is done by ecraseur, or by a wire sufficiently heated by galvanic current. We generally use the latter in "Martha," though we have many complaints to make against it, and have always a common wire ecraseur in reserve in case of failure of the galvanic battery. The mass is seized by vulsella, and

pulled down as far as it easily can be: the wire is passed around the base as high as to just keep clear of the pouch of Douglas and the bladder, and the amputation is effected by screwing up and taking in the wire. Bleeding rarely requires special treatment: it is arrested by plug, and we have not had occasion to use anything else: but it may be necessary to use ligature, or compressing forceps left attached for some hours. The vagina is washed out with antiseptic lotion twice daily, and healing encouraged by rest in bed, or perhaps by cauterisation.

I have said that by these operations we do not hope to cure, but to do substantial good for a time. Unfortunately the time is generally not many months, rarely for a year. But I have known cases where the disease has atrophied, and good of substantial kind has lasted for much more than a year—quite as much good as comes from operations intended to be more radical, or even to cure.

CASE OF CERVICAL PARAPLEGIA RAPIDLY FATAL.

By JONATHAN HUTCHINSON, F.R.S.,
Consulting Surgeon and Emeritus Professor of Surgery to the London Hospital.

A CASE is recorded in the St. Bartholomew's Hospital Reports, Vol. XVIII., by Dr. Gee and Dr. Abercrombie, of which the following are the abbreviated particulars:—A child, aged nearly five years, died after an illness of about three months' duration, which had begun with weakness of the right arm and slight drooping of the right upper eyelid. He had no headache, not much pain, and but little increase of temperature. The pupil of the right eye did not dilate well when shaded. There was no loss of sensation in the arm. Suddenly, at the end of six weeks, he lost the use of his legs, and his breathing became wholly diaphragmatic. He lost sensation in his legs, passed his urine and fæces under him, and had priapism when his legs were moved. He perspired very freely on the head, and on some occasions on the left side only. The right ear was hotter than the left. The condition of the upper extremities remained as at first. A swelling was noticed on right side of lowest part of neck, and the diagnosis, which at first had been infantile paralysis, was changed for that of strumous disease of the vertebræ. The knee-jerk had been lost, and, excepting the priapism, there had been absence of all cutaneous reflexes. The *post-mortem* revealed a malignant growth, which had probably commenced external to the vertebral canal, and had passed through the foramina into it. The cord was pushed aside, reduced in size by pressure, and very soft. There were other growths in the pleura and in the lung. Mr. R. W. Parker, after microscopic examination, pronounced it an alveolar sarcoma.

This case calls to my mind a not dissimilar one which I watched with great interest about a year ago. The patient, Captain B., was about 35 years of age. He had lived hard, and some years before had possibly suffered from syphilis. On account of a suspicion in this direction, he was sent to me by Dr. Walsh. He walked into my consulting room apparently ailing but little. His left arm was weak, indeed almost paralysed. His neck was held somewhat stiffly, and there appeared to be a bulging to the left at its root. This he explained as the result of an accident some years before. The weakness of the arm had only been noticed for a week or two when he came to me. I sent him into lodgings, and at once commenced the administration of mercury and iodide of potassium.

The paralysis rapidly extended. In a week he had lost the use of both arms, and was failing in his legs also. In another week he was helpless in all his limbs, unable to void his urine, or when purged to retain his fæces. His pupils were rather small and did not dilate when shaded. He perspired very profusely and almost constantly in all parts. Sensation was lost, and the catheter, which was used daily, was not felt in the least. It was thought best to explore the swelling in the neck, and this was done by an incision, under ether, down to the vertebræ, but neither abscess nor tumour was found. The patient was seen in consultation twice by Sir James Paget, and once by Dr. Hughlings Jackson. He lived about three weeks from the time of his coming up to London with his left arm weak. He died from progressive failure of the muscles of respiration. The diaphragm failed first, and his abdomen sank during inspiration and rose in expiration. Gradually the muscles of the chest wall failed from below upwards. For the last day or two he was able only to move the upper ribs, and could not get breath enough to say more than a word at a time. He had to be propped up in bed in a semi-erect position, and became breathless at once if he slipped down. During the latter period his head and upper part of neck were really the only parts of which he retained any consciousness. He died a most painful death, retaining full control of his mental powers to the last. Unfortunately we did not succeed in obtaining an autopsy. I am strongly inclined to suspect that a malignant growth was present, and this I believe was the opinion of Dr. Hughlings Jackson. The history of syphilis was doubtful, whilst that of an injury was very definite. Although we poured in iodide of potassium and gave mercury, both by the mouth and by inunction, most freely, not the slightest arrest of the progress of the paralysis occurred. No other syphilitic lesions were present.

I had never before witnessed such a definite form of brachial paraplegia as occurred in this case. For a day or two our patient could use his lower extremities sufficiently to stand whilst both arms hung helpless by his side. The order of failure of his nerves of respiration was also most exceptional. I had never before watched a death from diaphragmatic paralysis in the first instance, and failure of the external muscles afterwards. Yet such was the order observed in this case, and it was in keeping with the previously observed fact that the arms failed before the legs. I have since had under care in the London Hospital, a case in which a similar state of things existed, but in a much less severe degree. In this, the cause was a crushing of the cord from a partial displacement of the cervical vertebræ, and the patient after a long illness recovered. I find on record a few other cases in proof that it is possible for the cord to be disorganised so far as the supply to the arms is concerned, whilst that for the lower extremities is to a considerable extent preserved.

ON THE OUTBREAK OF CHOLERA IN EGYPT.

By SURGEON-GENERAL MURRAY.

I WISH to add a few remarks to what I said at the last meeting of the Epidemiological Society, in reference to Dr. Hunter's opinion of the origin of the Egyptian epidemic, which I gather from a perusal of his reports to the Government, to which he referred us. There was a sharp outbreak at Mecca in the previous year (1882), which extended with the returning pilgrims, *viâ* Medina, to the Egyptian frontier. There is no official record of its having passed the frontier, but that does not prove that it did not pass it, and remain dormant

during the cold season, resuming activity as the season advanced, as it had done in 1865–6. Its appearance in the villages on the banks of the Damietta branch of the Nile, might thus have been expected, and its virulent explosion at the large fair at Damietta was rendered probable. The reports of Dr. McNally and Mr. Honman show its existence in several villages on the banks of the Damietta branch of the river, in the latter part of May, and during June. The sudden outburst of the disease at the fair, which had existed for eight days on the 22nd June, its appearance at Port Said on the 23rd, amongst people who had returned from the fair, and the general spread of the disease to the neighbouring villages, and gradually over the country, in the natural course of human intercourse is a literal transcript of the accounts of many of the severe epidemics that have raged over India, particularly that of Hurdwar in 1879. I see no necessity for calling in the aid of a spontaneous origin to account for the outbreak in these cases, and consider the proof of communicability sufficient to show that it is not an endemic disease. If frequent recurrence in a place constitutes an endemic disease, then is small-pox endemic in Bengal, and venereal disease endemic in London, for these diseases are never absent from those places.

I am the more anxious to continue my observations on Dr. Hunter's valuable paper, because, though I am opposed to what may be termed his theoretical views of the spontaneous, or endemic, origin of cholera and its non-communicability, I cordially concur in the great advantages of sanitation in restricting the dissemination of the disease ; and in condemnation of the existing quarantine regulations, as entailing great misery on individuals, much loss to commerce, and being, at the same time, inefficacious in preventing the spread of the disease. When the subject was first agitated in India, as I was satisfied of the contagious nature of cholera, I advocated the institution of quarantine measures, such as had been sanctioned in Europe against plague. I carefully watched their operation, and found that they did not materially delay the spread of the disease. In theory, the principle of isolation is the surest indication of treatment ; but in practice, it is not possible to carry it into action, in reference to cholera, without intercepting *all* communication, which in an open commercial country cannot be done. The disease, in its incipient stage, may be transported by rail or steamer for a thousand miles without being recognised ; besides, from our increased knowledge of the ordinary channels through which it is communicated, and the little danger from personal contact, more efficient and less injurious means may be adopted to arrest the dissemination of the disease. Those in use by the British Government are in the right direction ; but that any regulations will supply a sure protection, is not to be anticipated ; but a greater degree of protection might be secured with less inconvenience and enquiry than the present quarantine regulations occasion. During the four epidemics of 1877–78–79–80, in the whole of India 154,986 villages were attacked, in 58,972 of these only one death occurred, and in 20,596 only two deaths occurred ; the total mortality in the four years was 1,380,226. One of Dr. Hunter's objections to quarantine carries great weight, and is, in my opinion, of much importance. I allude to its interference with the power of removal from the infected locality ; which measure Dr. Hunter mentions as having been so successful with the European troops in Egypt, during the late epidemic. This measure was first introduced in India in 1862, but for some time it met with considerable opposition. The military authorities objected to the responsibility of the removal resting with the medical officer ; the regimental officer objected to the trouble and inconvenience the movement into camp occasioned them ; and some of the medical officers who denied the contagious nature of the disease, and therefore considered removal useless, objected on account of the danger to the men from exposure to the sun and rains. In consequence of this opposition the Government appointed a commission (of which I was a member) to revise these regulations. Their recommendations were approved by Government, and have been in force in India since 1869, with manifest benefit to the Army, in considerable saving of life, and with the unanimous approval of all parties. I am glad to see that the British Government have now issued similar instructions applicable to their troops in all parts of the world. I have no doubt that Dr. Hunter's report has influenced this important decision, and I confidently expect that this example will be followed by all European states.

AMENORRHŒA AND VICARIOUS MENSTRUATION.

By GEO. GRANVILLE BANTOCK, M.D., F.R.S.C. Ed.,
Surgeon to the Samaritan Free Hospital.

My attention has been arrested by Dr. Wilks' note, under the above heading, in the *Medical Times* of February 9th. Dr. Wilks tells us, he has been much impressed with the practical importance of the lecture delivered by Dr. Matthews Duncan, and published in the Journal of the 2nd instant, and that, "feeling so much in accord with the sensible opinions propounded therein," he trusts these opinions "will find due weight on the minds of the younger members of the profession."

Treating of the subjects in inverted order, Dr. Wilks says of amenorrhœa, "I will only say a few words, since it is treated as a *substantive* complaint by many gynæcologists. For my own part, I know nothing of such a disorder, nor of such remedies as emmenagogues." I was under the impression that I had been taught, as a student, that amenorrhœa was *not* a substantive complaint ; but when I read such words coming from so careful a writer as Dr. Wilks, I thought within myself "surely I have not been mistaken in this matter." So I turned up some of the text books at my side, and here is the result.

Barnes tells us that the terms "amenorrhœa, menorrhagia, and dysmenorrhœa, like so many others we are obliged to use in medicine, do not represent any definite disease, but are simply general descriptions of symptoms." (1st ed., 1872, p. 178.)

Gaillard Thomas says, "From what has been already said, it is manifest that amenorrhœa is not a disease but a symptom. (5th ed., 1880, p. 638.)

Graily Hewitt teaches the same ; while Hart and Barbour, under the heading, "Amenorrhœa, Menorrhagia, and Dysmenorrhœa," say, "These three subjects, to which this section is devoted, are *not diseases*, but are symptoms of a large number of the more or less well ascertained pathological conditions already considered. (1st ed., 1882, p. 536.)

Such, then, is the teaching of our text books, and I cannot believe that there are many gynæcologists who treat this condition as a "*substantive* complaint."

With regard to vicarious menstruation, Dr. Wilks tells us that he has "always denounced the absurdity, as well as the error in fact, of a belief in this imaginary disorder." In this he is scarcely in complete accord with Dr. Duncan, who admits that "no doubt bleedings may

occur at what should be menstrual times. . . . . If there is a surface weak or predisposed to bleed, it may bleed during the excitement of a period," which is pretty much all that is contended for.

On this subject I would refer Dr. Wilks to a very remarkable case recorded by Dr. Barnes (p. 169, 1st ed.), as well as for references to other cases.

My own knowledge of this condition is limited to two cases, as follows :—

About fourteen years ago I was hastily summoned to see a lady who had just vomited some blood. The quantity was small and was thoroughly mixed with the contents of the stomach—only watery mucus. After enquiry into her condition, I was able to relieve her anxiety by telling her it was probably due to her commencing pregnancy. It was just a month from her last menstrual period. In the following month there was a recurrence of the same phenomenon, viz., vomiting of a fluid containing blood, several times, and for one or two days. In her next pregnancy she experienced the same thing at the end of the first month. She was not subjected to any treatment for it. It is, perhaps, worthy of remark that she was in the habit of menstruating rather freely.

More remarkable, however, is the following :—

In December, 1881, I removed a soft fibroid (weighing fifteen ounces) by enucleation per vaginam from J. M., æt. 54. She was a very intelligent woman, and reported that for three to four years, up to the age of eighteen, she menstruated regularly : that the menses then ceased, and she had no more discharge from the vagina till the year 1878 (she would then be 51) when she had a very severe flooding in the month of June ; that, from the age of 21, and till her 47th year, she bled from the mouth and nose with great regularity every month ; and that this bleeding was not continuous, but occurred at frequent intervals, extending over two or three days. The bleeding in June, 1878, was the first symptom of the presence of the fibroid.

It is well known that menstruation takes place without ovulation, that ovulation goes on without menstruation, and that there is no absolute dependence of the one upon the other.

It appears to me, then, that the term vicarious menstruation is a very good one for certain cases, and that it is quite as correct in its application as many terms which are generally accepted, but which are indefensible on any ground but that of usage.

REPORTS OF
HOSPITAL PRACTICE IN MEDICINE AND SURGERY.

UNIVERSITY COLLEGE HOSPITAL.

CALCULOUS PYELITIS AND CYSTITIS—DEATH—AUTOPSY.

(Under the care of Mr. HEATH.)

(For these notes we are indebted to Mr. VICTOR HORSLEY.)

JAMES H., a traveller for a timber merchant, aged 43, was admitted into the hospital on February 6th, suffering from difficulty in, and increased frequency of, micturition, and with pain in the region of the kidneys.

His family history was good : his own personal history showed that he had had two attacks of gonorrhœa, the last of which was very severe ; he had a sore on the penis at the same time, with glandular swelling, but no suppuration. This attack lasted about three weeks. He has always experienced some soreness along his urethra ever since the second attack, and this has always been aggravated on his "catching cold." He appears not to have suffered from any secondary affection. He is a great drinker, both of beer and spirits ; has to work about seventeen hours a day, and a good deal of walking to do.

He was an in-patient in the hospital, under Mr. Barker, last September, being admitted for retention of urine, due to the impaction of calculi in his urethra. On his admission at that time he had been drinking freely ; the bladder was distended, reaching nearly to the umbilicus. A No. 2 catheter was passed, and a quantity of ammoniacal urine being drawn off ; Mr. Barker was sent for and removed the urethral calculi, afterwards passing a No. 6 catheter, and drawing off seventeen ounces of foul urine, having a sp. gr. 1·007. His stricture was divided a few days later. This was followed by some slight rigors : his condition improved during the next few days ; the urine became more healthy, and a No. 10 could be passed easily ; he was discharged in this condition.

After leaving the hospital, he enjoyed good health until about one month ago, when he again had difficulty in micturition, the stream sometimes stopping suddenly, and then going on again, and causing pain. He has had increased frequency of micturition, both day and night ; and during the past few days, he has had much pain in his loins. These symptoms have all become aggravated since their first onset : vomiting has set in and occurs independently of food ; he has been very drowsy.

His present condition is as follows :—

He has considerable and constant pain in both loins, which runs down in the direction of the ureters, over which there is some tenderness, and especially on the left side ; there is no enlargement on either side over the kidney region. He is passing water eighteen times in 24 hours ; sometimes the stream stops suddenly ; there is generally a little pain at the commencement of micturition and during the act.

February 7th.—He slept very little during last night ; he was passing small quantities of water every ten minutes, the act being accompanied by burning pain. He complains of pain over the left kidney ; the hands are cold, the feet warm, the skin is hot and dry. His bladder was washed out with a solution of Condy's fluid.

February 8th.—Patient is weaker ; he makes great straining efforts to pass water, but small quantities only are passed. The efforts cause considerable dyspnœa. He answers questions in a whisper, and seems dull. A purge and a hot-air bath were given.

February 9th.—Patient lies in a semi-comatose condition. He vomited yesterday afternoon. A hot-air bath was given at mid-day. He became more and more comatose, and died quietly about 6 p.m.

Autopsy (made by Mr. Horsley).—The dura mater was slightly yellow in centre ; there was an excess of sub-arachnoid fluid, with marked wasting of the convolutions. All the vessels throughout the white and grey matter of the brain were overfilled, but there was no diminution in the density of the brain substance, nor any œdema. *Lungs :* Friable, slightly œdematous and hypostatically congested. Trachea and bronchi contained a quantity of muco-pus : their mucous membrane was intensely congested. Both pleural cavities were smeared over with thick purulent fluid. *Heart :* Right side contained a quantity of black or slightly decolourised *post-mortem* clot ; valves and muscular substance were normal. Left side : Valves normal ; muscular substance mottled and softer than usual. *Liver :* Rounded, the margins of the lobules were still distinct ; the substance was yellowish and extremely friable. *Spleen :* Large, swollen, and with an excess of fibrous tissue ; substance friable. *Kidneys :* The left was greatly swollen, and of a dark maroon colour.

The pelvis was of a dark blackish red colour, intensely congested; the infundibula dilated here and there, containing small irregular calculi, the largest of which measured eight by five millimetres; the kidney substance was not destroyed by pressure, was œdematous, congested, and contained numerous abscesses, averaging four to five millimetres in diameter. Right kidney: Pelvis dilated; mucous membrane of a dark reddish colour and intensely congested; all the infundibula contained calculi from two to eight millimetres in size. The calculi consist of amorphous collections of semi-crystalline urates. The kidney substance was swollen, congested, and œdematous. *Ureters:* Both were considerably dilated, their lining membrane was intensely congested, and of a slaty grey colour. *Bladder:* The mucous membrane was very rugose, the bases and margins of the rugæ being of a dark slaty grey colour; the wall was about twice its normal thickness. *Prostate* normal. *Urethra:* Membranous portion was depressed into pockets by the scars of previous ulceration; over the posterior part of the bulbous portion the mucous membrane was completely ulcerated. At the junction of the posterior and middle thirds of the penile urethra there was also some ulceration, and the rest of its extent, penile urethra was marked by numerous pockets and scar depressions. The sub-mucous tissue throughout was very hard and dense, and about two millimetres thick. *Testes* and *epididymis* normal. *Stomach:* Mucous membrane covering the rugæ was swollen, semi-gelatinous in appearance and extensively congested. The only abnormal condition throughout the small intestine was a little chronic congestion.

Medical Times and Gazette.

SATURDAY, FEBRUARY 16, 1884.

The General Medical Council is summoned to meet at two o'clock on Tuesday, March 25th, the Executive Committee the day before (March 24th), and the English Branch Council on the morning of March 25th.

Sir Trevor Lawrence did good service in asking the Home Secretary, on Monday last, by whose authority, or under what instructions the Public Prosecutor supported the criminal information against Dr. Bower and Mr. Keates; and whether the medical officer of the Treasury, or any other medical adviser, had been consulted before the Public Prosecutor, or, to follow the official exactness of Sir Henry James, the Director of Public Prosecutions appeared in the case. Sir Trevor Lawrence also asked whether any compensation would be given in the case; probably adding that part of his question simply in order to emphasise the injustice done; as the intervention of the Public Prosecutor precludes, we believe, all action for damages or compensation.

The question was answered by the Attorney-General, and his reply is for several reasons very noteworthy. We learn that the Home Secretary had nothing to say to the Public Prosecutor—we beg Sir Henry James's pardon, but ordinary mortals cannot spare the time to always say the Director of Public Prosecutions. That legal official with the long name acted entirely on his own responsibility; he did not *institute* the proceedings in any way, indeed when first applied to he refused to act. But when the parents had obtained a summons from a magistrate, they again went to the Director and pleaded *in formâ pauperis* for help. "They were American subjects" they stated, "and had no means of employing legal assistance." The heart of the Director was moved, and he thought it right they should have "aid in a qualified sense;" so he gave "special directions"—in what sense special does not appear—that "a solicitor should attend, and see that all the evidence, whether it told in favour of or against the accused, was placed before the magistrate." This "special direction" seems fair enough, supposing the Director was justified in giving any countenance to the case, and supposing that he took any care to see that his direction was fairly carried out.

But to the average mind it appeared, we more than suspect, that the prosecution was urged with "special" acrimony and insistance; and we venture to say that the public will be greatly surprised, and a new terror will have been added to "the law," if one of the functions of the Director of Public Prosecutions is to be to afford legal assistance to people who, whether they be American subjects, or subjects of any other State, when they have failed to obtain a verdict in a civil action apply to him for means to institute a criminal prosecution in the same case. Further, it is remarkable that the Attorney-General did not state that the Director had sought any medical advice whatever in the matter; but, nevertheless, in his opinion, the Director "did rightly, and was entirely free from blame." Sir Henry James went, in fact, so far as to say that the dismissal of the case was chiefly owing to the representative of the Director having placed all the facts fully and impartially before the magistrate. Did the "representative" of the Director conduct and assist the defence also?

Innumerable householders in London will sympathise with, and feel grateful to, Lord Longford, who appeared in the House of Lords, a day or two ago, in the character of "the perplexed householder" seeking for trustworthy information as to the rating powers of the Metropolitan Water Companies. He had no dispute, he said, with any of the companies, but he had to pay Queen's taxes, parochial rates, and water rates upon different valuations of the same premises, and not one of these corresponded to the rent paid; he therefore asked for, and is to have, a return, showing the charges that the several Metropolitan Water Companies "are authorised by law to levy, quoting clauses of Acts of Parliament under which their rating powers are claimed, with sketch map coloured to show the districts supplied by each company." The public will be able to obtain this "parliamentary paper" when it has been presented in the House.

Neither of the Bills introduced this year to amend the Cruelty to Animals Acts in any way touches the Vivisection Act. Mr. Anderson's short Bill has for its

object the suppression of "pigeon shooting." It provides that any person who shall either in any place kept or used for the purpose, or elsewhere, shoot at any bird liberated for the purpose, or who shall in any manner encourage, aid, or assist at such shooting, shall, on conviction, forfeit and pay a penalty not exceeding 5*l.* for every such offence. It is the same measure that last year was passed by the House of Commons, but thrown out by the Upper House. Mr. Labouchere's Bill, which is still more brief than Mr. Anderson's, simply is for the extension of the Cruelty to Animals Act, so as to make it apply to every animal, whether domestic or wild, exhibited for gain: the object being to bring under the Act, the wild beasts kept in menageries, and the bears and other animals shown about the country.

It is a refreshing novelty to find the Government taking, without any direct and continued pressure from without, a positive step forward in the protection of the public against the unrestricted sale and use of poisonous "specifics" under a Government stamp. The Vice-President of the Council, Mr. Mundella, has stated in the House of Commons that the attention of the Privy Council having been directed to some cases of death, in children, from the administration of a patent "specific for whooping-cough," a Bill dealing with the whole subject of the sale of patent medicines of a dangerous nature will shortly be introduced in the House of Lords. It would be very difficult, we suppose, to obtain, and perhaps ungenerous to ask for, a return of the number of deaths caused by patent medicines—say, within the last ten years, so that an idea might be arrived at as to the loss of life needed to stir the Privy Council into action.

A well-attended Meeting of the Clinical Society on the 8th of February was occupied, throughout a somewhat prolonged sitting, with the subjects of obliterative arteritis and pyrexial syphilis. Papers were read on the former by Mr. Pearce Gould and Dr. Hadden. The case which formed the text of Mr. Gould's paper had been previously exhibited at a meeting of the Society in November last, whilst the disease was in an acute stage, and the patient was again present to illustrate the subsequent course of the arterial changes. The discussion, which was well supported, turned chiefly upon the influence of local pressure upon arterial trunks, in the production of thrombosis or arteritis. A paper by Dr. Burney Yeo, upon a case of pyrexial syphilis, also attracted close attention, both from the interest attaching to the subject, and from the clear and concise style in which the facts, and the remarks upon them, had been written by the author. Several speakers in the subsequent debate had had experience of the occurrence of fever in syphilis, and cases were also cited of anomalous rashes due to the same cause, which had given rise to pardonable errors in diagnosis from their exact resemblance to the eruptions seen in small-pox, erythema nodosum, &c. An interesting series of living specimens was exhibited:—Symmetrical arrest of development in the third metacarpal bone of both hands, by Dr. J. K. Fowler; acne varioliformis, by Dr. Stephen Mackenzie; keloid, by Dr. Charlewood Turner; a case of diffuse syphilitic infiltration of the tissues of the neck; and Mr. Pearce Gould's case of obliterative arteritis.

Two very suggestive remarks were made in the course of the debate on Dr. Yeo's paper, the one by Mr. Jonathan Hutchinson, and the other by the author himself. Mr. Hutchinson referred to the possibility of pyrexia in the course of syphilis being at times overlooked, owing to the somewhat deficient manner in which clinical investigations are wont to be made in surgical wards. The observation is, no doubt, true, and the explanation of this regretable truth probably lies in the fact that such investigations are generally left in the hands of junior students, whilst in the medical wards the work is done by those more advanced.

There can be no reason, however, against all clinical cases being examined *thoroughly*, even though unskilfully, by the commencing student, and if a routine practice of complete examination were more generally adopted, it would be impossible for sores upon the genital organs to remain for a long time undiscovered. Such an occurrence as that described by Dr. Yeo, and by him attributed to the constant presence of ladies in the wards, would certainly be less likely to occur in future.

At the Medical Society, on Monday evening last, Sir Joseph Fayrer, F.R.S., President, in the Chair, Mr. Bryant read a short paper on the "Treatment of Irreducible Hernia, and an improved method of adapting a Truss in Hernia generally." He did not consider these forms of hernia as irremediable, nor think that they should be handed over to the mechanician. Every case, he said, was capable of reduction unless adhesion had been formed in the sac. He recommended rest in bed for a period varying from a few days to a few weeks, with restricted diet, and the continuous use of cold applications. In this way, the size of the hernial protrusion was lessened, masses of fat were absorbed, and when all had been accomplished, then, a cast of the remaining tumour should be made in plaster of Paris; metal casing was next made on this, it was covered with wash-leather, and adjusted to a spring; thus a perfectly fitting truss was obtained, which grasped the tumour, pressed on it on all sides equally, and while it protected that which could not be reduced, prevented further protrusion. Its convex pad, furthermore, never got displaced like many forms of trusses. Specimens of the truss were shown.

At the same meeting Mr. Hutchinson read an exhaustive paper on "Lupus Disease of the Skin." He began by defining what he himself meant by lupus, and his subsequent remarks were intended to enlarge the term as generally used. Mr. Hutchinson uses the term lupus, as a clinical definition for a superficial disease of skin and mucous membrane—differing from rodent ulcer, which older authorities used to include under lupus, in that, however long it may last, it never

eats in deeply—of very slow growth, having a growing infective margin, and leaving a scar on those places over which the disease has passed and expended itself. He then passed in review all the diseases having these essential features among others, showing portraits and illustrating the varieties by drawings. Each variety was separately described, its own peculiar characteristics being given, as well as the more general features which brought it within the group. Lupus begins as an ordinary inflammation, and it gets its peculiarities from the soil (patient's constitution) in which it grows. It is easily set up, slight irritations, such as cold winds, stings of gnats, &c., sufficing in a constitution predisposed for it. The cellular infiltration which is found is not a cause but a consequence of the disease; it is not infectious, or due to contagion, but when established it produces the special form of new growth—apple-jelly deposit—which is so characteristic of the malady. A scar is always left behind in those places from which the disease is receding; its amount and thickness vary according to circumstances, and the intensity of the process. The infective vigour of the new deposit is very great, for it hardly ever stops spontaneously. Mr. Hutchinson spoke of lupus vulgaris, lupus erythematosus, acne lupus (the disseminated follicular lupus of Dr. Fox), eczema lupus, lupus mutilans, lichen lupus, lupus lymphaticus, and lupus pigmentosus (Kaposi's disease), interesting specimens of which last form were shown to the Royal Medical and Chirurgical Society a few weeks ago by Dr. Radcliffe Crocker.

At the meeting of the Royal Medical and Chirurgical Society, on Tuesday last, Dr. Broadbent made a communication on alcoholic poisoning, illustrating the subject with histories of seven fatal cases. The alcohol had been taken in unusual excess, most of the patients were females, of a sedentary mode of life. One of the patients was a gentleman, who spent most of his time in bed. Dr. Wilks was quite familiar with the disease; but in one respect, at least, his experience differed from that of Dr. Broadbent; his patients had all recovered; indeed, he had been struck with this fact, that under proper treatment, which consisted chiefly in withholding alcohol, even the severe cases quite recovered. Dr. Buzzard and Dr. Barlow spoke to the same effect. The President also showed some of Dr. Straus's microscopic preparations, illustrating his recent researches on cholera in Egypt, as chief of the French Scientific Mission. A description of these will be found in our report of the Society's proceedings at their Tuesday meeting. All those who had examined the preparations agreed with Mr. Horsley, that Dr. Straus had correctly described them; but the Fellows were also agreed, that it was quite impossible to say that these germs were the special germs of the cholera morbus.

That Surgeon-General Hunter has thoroughly earned the distinction of Knight Commander of the Order of St. Michael and St. George, which we understand is about to be conferred upon him, will be the unanimous verdict of the medical profession; and this speedy and spontaneous recognition of honest labour in the service of his country adds immensely to its value. His old hospital (Charing Cross), has done itself, as well as him, honour in electing him, a few days since, to be Honorary Consulting Physician.

The adjourned debate on Surgeon-General Hunter's paper on cholera was resumed on Wednesday evening last, when Sir W. Smart, Dr. Lawson, Dr. Scriven, Dr. Thrupp, and Dr. Longhurst continued the discussion, and Sir W. J. Hunter replied. It is a matter for great regret that the debate could not have been adjourned for a day or so, to permit many other experienced men to express their views, but the President ruled that this was contrary to the laws of the Society. At the close of the meeting, Sir W. J. Hunter read a letter from Dr. George Buchanan, F.R.S., containing an extract from Bacon's "Silva Silvarum," affording a striking confirmation of his own views as to the endemic nature of the disease.

A meeting of the Medico-Psychological Association was held at Bethlem on the 5th instant, Dr. Orange, the president, occupying the chair. Dr. Savage read a paper on the constant watching of suicidal cases, in which, besides discussing the best methods of preventing suicidal patients, both by day and by night, from carrying out their intention, he spoke of the influence that determined measures of watchfulness exercise in reminding the patients of their purpose, and of prompting, and almost daring, them to make suicidal attempts. The existence of this influence was admitted and testified to by Dr. Rayner. Dr. Ley, of Prestwich, pointed out that suicides do not, as a rule, occur in what are known as suicidal cases. These are too well supervised to get a chance. The majority of suicides that occur in asylums are committed by patients in whom no suicidal tendency has previously been suspected. The general outcome of the discussion was, the advisabilty of making the precautionary and preventive measures stringent, but of keeping them as much as possible from the knowledge of the patient. Dr. Gasquet related several cases in which delusions of grandeur of a very pronounced type appeared in patients, the subjects of gross brain disease, such as thrombosis, sclerosis, and syphilis. Beyond a suggestion from Dr. Hack Tuke, that the grandiose delusion in such cases, and in cases of general paralysis, were in common dependent upon affection of the same group of convolutions, little elucidation of these cases was obtained from the discussion.

A paper, by Dr. Herbert Major, "On the Results of the Collective Record of the Causation of Insanity," brought together the figures in the statistical tables drawn up by the Association, as supplied by the superintendents of asylums for several years past. The main contention of the paper was, that as the percentage of cases attributed to any one cause remained fairly constant from year to year, the value and correctness of the tables must be admitted. This conclusion was vigorously contested by Dr. Mercier, who declared Dr. Major's conclusions to be absolutely fallacious, being founded upon data that were untrustworthy to the point of complete worthlessness. This view was supported by Dr. Huggard and Dr. Savage, and, in spite

of a protest from Dr. Hack Tuke, appeared to be in harmony with the opinion of the majority of members present. The members of the Association subsequently dined together at the Holborn Restaurant.

The third "Congress für innere Medicin" will be held this year at Berlin, from the 21st to the 24th of April, under the presidency of Prof. Frerichs. The following are the subjects put down for discussion:—"True Pneumonia: its Ætiology, Pathology, Clinical Characters, and Treatment;" "Poliomyelitis and Neuritis," and "Nervous Dyspepsia." Besides discussions on these subjects several papers are promised, amongst which are the following:—"On School-Hygiene in England, especially with reference to Infectious Diseases," by Dr. Hermann Weber; "On Reflexes," by Dr. Rosenthal, of Erlangen; "On the Localisation of the Functions of the Brain," by Dr. Goltz.

The Otologists will hold their third International Congress at Basle, from the 1st to the 4th of next September, and a strong committee, in which Englishmen will notice with pleasure the names of Mr. Dalby and Dr. Urban Pritchard, has been formed to organise a successful meeting. The Otological Congress has a four-yearly orbit; and this year, for the first time, it is in conjunction with the triennial International Medical Congress, so that it is hoped that many visitors from America and other remote countries, after visiting the latter at Copenhagen, from August 10th to 16th, will, after a leisurely progress across the Continent, present themselves at Basle on September 1st. If the two Congresses keep strictly to their respective periods, it will naturally be close upon the end of the century before they again occur in the same year. Gentlemen who wish to read papers at the Basle Meeting are requested to communicate the subjects which they intend to treat to the president, Dr. Burckhardt-Merian, of Basle, before May 15th, as it is proposed to issue a full programme of the Congress at the beginning of June. This programme will be sent to anyone who announces his intention of being present at the Congress. Besides the reading and discussion of papers, opportunities will be given for exhibiting instruments and specimens.

Those interested in the success of the new movement known as the Volunteer Medical Organisation, have every reason to be satisfied with the reception which the deputation from that body met with, on Wednesday last, at the hands of the Marquis of Hartington. The object of the deputation was, to urge upon the Secretary of State for War the desirability of forming a medical corps, to occupy the same relation to the Volunteer Forces as the Army Medical Department and Army Hospital Corps do to the regular Army, to point out how useful in time of war such a trained reserve might be, and to ask for the grant of a capitation allowance for efficient members of the corps; and further, for practical support in the shape of the issue of ambulance *materiel*. Lord Hartington, in reply, thought the scheme promised great advantages, both to the Volunteer Service and the country generally. He could not commit himself to any definite opinion until the details of the scheme had been worked out, when he had no doubt the War Office and military authorities would be willing to render every assistance in their power.

During last week out of the 28 great towns of England, as many as 17 had a death-rate of over 20 per 1,000, and their aggregate rate was 20·6. Of the eight large Scottish towns, on the other hand, the aggregate death-rate was 24·7, and only one of them had a death-rate below 20·0. This excess in the mortality of the Scottish over that in the English large centres of population is not to be entirely explained by the greater prevalence of zymotic disease in the former, though the zymotic death-rate of the 28 towns was only 2·4, and that of the eight towns as high as 4·0. The population of the eight Scottish towns is as near as possible one-seventh of that of the 28 English towns, and yet during the past week 23 cases of diphtheria and 14 of fever were registered in the former, as compared with 28 cases of diphtheria and 44 of fever registered in the latter. There is, no doubt, much room for sanitary reform in Scotland, though the current return must be admitted to be an exceptionally bad one.

Of the health of London during the past week, there is not much to be recorded. The number of deaths was 516 below the ten years' average, and the death-rate accordingly keeps satisfactorily low, viz., 19·5. The zymotic death-rate was 2·4, and has steadily kept somewhere about that level for the last six weeks. The numbers of deaths from whooping-cough, 78; and from diphtheria, 19, still continue excessive, compared with the returns from the other 27 great towns The mean temperature of the week was nearly two degrees above the average, although the clouds robbed us of seventy-two seventy-thirds of possible sunshine.

The nursing arrangements of Charing Cross Hospital have, unfortunately, been so prominently brought before the public during the past seven or eight months, that we feel sure our readers will rejoice to hear that a solution of the difficulties has been at last arrived at. It will be remembered that in November last the Council passed a resolution terminating the agreement with St. John's House at the end of June next. On Wednesday last the treasurer, who has all along made no secret of his bias in the matter, asked the Annual Court of Governors to invite the sisters who had deserted the hospital last June, to undertake the nursing in the future. To this resolution an amendment was proposed, that the nursing be entrusted as heretofore, to St. John's House, and upon being put to the meeting, the amendment was carried by an overwhelming majority, a proposal by Mr. W. H. Smith, M.P., to refer the whole question to a small committee for further report, having in the meantime been negatived.

Probably the tactics adopted by Mr. Few, and his seconder Mr. Fladgate, had a good deal to do with this result. Knowing the weakness of their own case, they

tried to shift the real point at issue, and raised the cry that it was a case of the medical staff setting themselves in opposition to the will of the governors. The statements, by which it was attempted to support this theory, bore their own refutation on the face of them, and were of a kind altogether beneath our notice. If we understand the matter aright, the position of the staff was simply this. Was it in the best interests of the patients that a set of ladies, who, for a mere pique, had deserted their work, should again be entrusted with the charge of nursing the hospital, or should those who had, during the last few months undertaken that work, and given every satisfaction in the performance thereof, be invited to continue at their posts? It is difficult to understand how any one in his sober senses could come to any other decision in such a matter than the medical staff did. The issue put before them was of the simplest kind. A horse that has once run away earns for itself the reputation that, when the occasion arises, it may do the same thing again, and the application of this general principle would make any one suspicious of the possible behaviour of the sisters of St. John the Divine in the future.

On Monday evening, the 11th instant, Mr. William Ireland Wheeler, the President of the Royal College of Surgeons in Ireland, gave a banquet in the Albert Hall of the College, in celebration of the centenary of the institution. The entertainment was honoured by the presence of His Excellency the Lord Lieutenant, several of the judges and members of the Irish bar, the Provost of Trinity College, Dublin, and other distinguished guests. The President of the College, replying to the toast of the Royal College of Surgeons, proposed in felicitous terms by the Lord Lieutenant, recalled the fact that in 1756 the Government established the County Infirmaries of Ireland. Subsequently the leading surgeons of Dublin formed a society and founded the college, to which a charter was granted on February 11th, 1784, and upon which examining powers were conferred two years later. Referring to probable medical legislation, the President observed that now, as on all former occasions, the College would be found desirous to assist in any way in promoting suggestions which were for the good of the public, while at the same time an endeavour should and would be made to preserve the functions of the College in their integrity.

A Berlin correspondent of an American journal gives some account of the surgical clinic of Prof. von Bergmann who, he says, has fully maintained the reputation of the chair of Langenbeck, to which he succeeded about a year ago. He believes in thorough antisepsis, and employs, wherever possible, his favourite antiseptic—corrosive sublimate solution (1 part to 1,000), which he first introduced at Würzburg, eight years ago. Into this the hands of operator and assistant are dipped, after thorough cleansing, and this is repeated several times during the operation, the parts of the person around the point of incision being subjected to the same treatment. Before and during the operation a spray of a three per cent. carbolic acid solution is continuously at play, covering surgeons and nurses, as well as the patient operated upon, with a fine drizzle. All instruments and ligatures are kept in an antiseptic solution during the operation except when in use. The operating table is covered with a heavy sheet of rubber, half an inch thick, which is easily and thoroughly cleaned, and kept free from septic infection. Chloroform only is the anæsthetic used, and is administered by means of a piece of flannel cloth stretched over a wire cone, about the size and shape of a very small bowl. Patients are not allowed to eat on the day of the operation before its performance. Nausea is comparatively rare, and deaths on the operating table are very seldom heard of. The head of the patient rests on a cylindrical air-cushion, which is found convenient as well as clean. Everything is immaculately clean. "The iodoform, which to an American seems to be used with such astonishing freedom, not infrequently, according to Berlin physicians, produces delirium, it is even charged with more serious results."

Whilst the plethora of young consulting physicians and surgeons in London is becoming a serious question with us, it would appear that in other countries and towns, and especially in Germany, a similar plethora exists, of unattached teachers in the very numerous schools and universities. With them, as with us, the junior appointments are eagerly sought for, and the frequently laborious duties attaching to them are performed with zeal and enthusiasm, and with no other reward than the small social distinction that such honorary public positions are supposed to carry with them. Professor Virchow has, at a recent sitting of the Prussian Parliament, called prominent attention to the existing state of things and raised the question of State recognition of the services of the Extraordinary Professors and Privat Docents in Germany. Such State aid would undoubtedly have a valuable result in retaining for their own schools the services of the most distinguished students, but at the same time it would tend to bring the medical profession still more under Government control than it is at present, a result which the recipients of State aid would themselves be most anxious to avoid. Possibly, as suggested by the editor of the *Berliner Klinische Wochenschrift*, the true remedy for the plethora of teachers is to be found in restricted admission to their ranks, since even the apparent hopelessness of success is not sufficient to check the ever-increasing number of recruits from entering the lists, under the present conditions.

The German Cholera Commission, under the direction of Professor Koch, arrived in Calcutta, on December 11th, after a short stay in Madras, where the existing arrangements for dealing with epidemics were closely investigated, although at the time no cases of cholera had occurred in the city. Every facility appears to have been afforded to the Commission in Calcutta, for carrying out its researches in the most effective manner, laboratories being at once established in the Medical College. The occurrence of one or two fatal cases of cholera in the hospital enabled pathological experiments to be commenced within two days

of the arrival of Dr. Koch and his fellow workers in India. The number of cholera cases in the capital city usually begins to increase about the middle of December, and hence, the material at the disposal of the Commission will probably amply suffice for the objects which they have in view.

Dr. Koch's fifth report, in which he gives further information as to the cholera bacillus, has just been published, and we hope to present an abstract of it to our readers in our next issue. In his previous report to the German Minister of the Interior, Herr von Bötticher, Dr. Koch tabulates the following as the immediate subjects for investigation. 1. Microscopical examination of as large a quantity of material as possible for the extension and proof of the discoveries made in Egypt of the occurrence of bacilli in the intestinal mucous membrane in cholera cases. Especially, also, investigation of the special properties of the bacilli in respect to their microscopical appearances, in order to arrive at a distinct differentiation of these from other bacilli of similar size and form. 2. Researches into the occurrence of cholera in animals. Repetition of inoculation experiments on different species of animals, with choleraic tissues; and especially by means of methods which have not hitherto been employed; as for instance, direct injection into the intestine. 3. Obtaining, by recultivation, the bacilli found in the intestine of cholera cases, and employing these recultivated organisms for inoculation experiments on animals. 4. Determination of the biological properties of the bacilli, especially the formation of spores, length of life, behaviour in different media and at different temperatures. 5. Disinfection experiments, to hinder the growth of the bacilli, or to render them innocuous.

In addition to these laboratory researches, Dr. Koch intends to devote his attention to a wider investigation. This will include—6. Examination of soil, water, and air in their relations to the infective material in cholera, in respect of the question whether this can possibly exist in certain cholera districts independently of the presence of human bodies, as for instance, in certain processes of decomposition in the soil. 7. Special researches into the cholera conditions prevalent in India. (*a.*) Connection of cholera in the endemic districts with special peculiarities in the population or their surroundings. (*b.*) Outbreaks of cholera in prisons, amongst troops, or on board ship. (*c.*) Conditions prevailing in the endemic districts, in places especially visited by cholera and in others especially free from it. (*d.*) The manner in which the spread of cholera takes place over the limits of endemic districts, and the routes by which the disease travels in India, and from India to other countries. (The intention of the Commission is to investigate especially the spread of the disease by means of religious pilgrimages, and, further, its spread along the great commercial and shipping routes.) (*e.*) The regulations which have been found conducive to the lessening of cholera in India, in the prisons, and amongst the troops, and the restrictive measures under which a striking reduction of the mortality of cholera has been effected in certain towns in India, such as Madras, Calcutta, and Pondicherry. Dr. Koch does not ignore the possibility of failure in his attempts to establish the identity of the cholera bacillus, but under any circumstances proposes to give especial attention to the practical points above enumerated.

The French Comité Consultatif d'Hygiène Publique has, on two separate occasions, reported against the employment of salicylic acid, even in small quantities, as an agent for the preservation of articles of food. As this conclusion has been much opposed by those interested in such employment, a sub-committee of the body in question has reconsidered the matter, and their reporter, Prof. Brouardel, has published their conclusions in a recent number of the *Annales d' Hygiène*. He observes that, although the beneficial operation of salicylic acid in certain diseases is fully admitted, the theory of its action is very imperfectly understood. It is however known, that when introduced into the economy it is eliminated by the kidneys and liver; and its warmest partisans admit that its use is contra-indicated in the subjects of those diseases, which prevent its due elimination, and thus give rise to an accumulation that in several instances has proved fatal. Moreover, elimination is sometimes impeded from unknown causes in persons in whom the functions of these organs work healthily; while in aged persons it is always very slow. Under any circumstances, only a portion of the salicylic acid is eliminated, the remainder undergoing combinations in the tissues, which, although they may prove therapeutically useful, and even for a time produce no evil consequences, could not be indefinitely prolonged without mischief ensuing.

Even small doses of the salicylate may prove dangerous to persons who eliminate it imperfectly; and Prof. Brouardel's investigations during several years past lead him to believe that such persons are largely on the increase. Since 1861 he has analysed the urine of all patients entering his hospital service, and his registers show that the frequency of albuminuria has more than doubled during the last twenty years. Now, these patients are not all condemned to an early death, for many recover, and others live for many years; and when examples are adduced of young and robust persons tolerating the daily use of from four to six grammes of the salicylates for months or years, we must not forget the aged persons and albuminurics, and individuals the subjects of various kinds of hepatic and renal disease, whose lives might be seriously compromised by such a regimen. The committee, therefore, believing that for such persons the daily use of salicylic acid would be highly dangerous, while even for those in good health there is no proof that it would be innocuous, recommend that its present prohibition should be maintained.

In a leading article on the recent case of Messrs. Bower and Keates, the *New York Medical Journal* for Jan. 5th draws attention to the efforts made for many years by Dr. Sayre to secure the passage of a statute, obliging persons who bring suits for malpractice

against medical men to secure the defendants against pecuniary loss in the event of failure of the suit. Such a provision, while not affording security against vexation and indirect loss, would doubtless go far towards checking frivolous prosecutions. "In so far as suits for malpractice are concerned; and, if we except abortion cases, in so far as criminal charges are founded on matters of medical practice, the annals of the prosecution of medical practitioners may be said to constitute almost an unbroken tale of malicious persecution." In England, at all events, the profession will scarcely admit the "exception" above mentioned; but there will probably be no dissent from the proposition that "as matters stand now, malice is almost the only thing needed to bring any practitioner at any time into a position where he must feel doubt and anxiety as to how the jury will view the testimony, and the painful certainty of earning a newspaper fame that will prove anything but pleasant." That civil suits may be instituted upon apparently slender evidence, is perhaps not altogether unsalutary. But a caution, in some degree commensurate with the interests involved, is usually exercised in the case of criminal prosecutions; and it is at least rare to see suits of this character commenced without there being something definite and tangible in the way of evidence to begin with.

If such a legislative safeguard as is afforded by the latent equity of ordinary judicial procedure be desirable in the interest of every citizen, it is peculiarly necessary to the members of the medical profession. To them a criminal prosecution, even though it fail, is peculiarly disastrous and specially harassing, because it strikes at the very root of the qualification which is absolutely necessary to the maintenance of their social position; and the practice of medicine implies and depends upon social position of one degree or another. Another man may be immoral in his mode of life, hard hearted, cruel or violent, a gambler or a roué, and these things may be known of him; but so long as his shortcomings are kept beneath the surface and are not obtruded within the circle of things which must be recognised, society will receive, and even welcome him, if he can produce other credentials for its favour. It is quite otherwise with the family doctor, whose life is necessarily, in one sense at all events, a public one, and whose value and usefulness must always depend so largely upon the extent to which he wins respect and trust. The mere fact of a criminal prosecution being brought against a man in such a position, implies a possibility from which his patients—such of them, at all events, as are best worth having—will shrink only less than he himself does. And though the suit fail ignominiously, it has brought with it a stigma which the world's uncharitableness—acting upon the assumption that where there is smoke there must be fire—will not quickly allow to fade, and which it will be ready upon slight provocation to revive.

It is probable that such a provision as that advocated by Dr. Sayre would, until lately, have had but little chance of becoming law in England; because it might have seemed practically to bar all chance of such actions being brought by persons of slender means. The appointment of a public prosecutor should meet this difficulty; it would be within that functionary's province to weigh the preliminary evidence put before him, and if such appeared sufficient, to institute the necessary proceedings on behalf of impecunious complainants, in the name of the State; but he should be directed to obtain such help from skilled assessors as would enable him, in any doubtful case, to decide in accordance with the real value of the evidence adduced. But it is scarcely probable that medical men would now be willing to advocate a measure by which their dearest interests should be submitted to an official whose haphazard decision, if unmodified by any assistance such as is to be derived from skilled technical advisers, might again sanction the institution of proceedings to be characterised as "persecution, not prosecution."

The sanitary history of the important district of Wandsworth, for the year 1882, shows that, although the health of the locality was not quite up to the standard of the year immediately preceding it, it was nevertheless remarkably good. Regarded solely from a statistical point of view, exceptional years are misleading, and as the year 1881 was credited with the lowest rate of mortality ever returned in any annual report for the district, the year under notice suffers to some extent by comparison with it. The less exalted vitality of the latter was, it appears, due to a greater prevalence and fatality of epidemic diseases, chiefly measles, scarlet fever, diphtheria, and whooping-cough.

Amongst the many excellent tables appended to the present report is one which exhibits the relative proportion per cent. of mortality amongst different classes during the six years 1877–82; it is as follows:—

	1877	1878	1879	1880	1881	1882
Nobility & Gentry	2·50	1·62	3·30	3·40	2·71	3·43
Professional Class	6·20	5·08	5·90	5·50	5·12	4·44
Middle Class ..	18·20	18·10	17·40	16·90	19·00	20·85
Industrial Class ..	73·10	75·20	73·40	74·20	73·17	71·28
	100·0	100·0	100·0	100·0	100·00	100·00

The report points out that a gradual diminution in the relative amount of mortality occurring amongst the industrial classes has been observable in the district for a considerable number of years; and as such a result, it goes on to say, is one of the most trustworthy evidences of sanitary improvement effected amongst that portion of the community in which it is most needed, it is satisfactory to find by the figures in this table that the reduction referred to was very much more considerable during the past year, notwithstanding the prevalence of a larger amount of epidemic disease, than in the previous year. Though great improvements in sanitation have been effected in this district, the report adds, there are many defects still waiting to be remedied, amongst the most important of which is the nuisance and danger to health arising from the manner

in which the sewers are ventilated at the expense of aërial purity in the streets, whilst in close association with this great intrinsic defect of the main drainage is the imperfection of the water supply, which, at the present time, deserves the serious consideration of the authorities.

Under the heading "Falsifying the Returns," the *New York Medical Record* makes a charge against the medical charitable institutions of New York, which, we fear, is not altogether inapplicable to places nearer home. The returns are exaggerated, "so as to create the impression that a greater amount of work is done than is actually the case. For example, a dispensary reports that it has treated 10,000 cases during a single year. The facts are, that the real number treated is about one-fourth, or even one-half, less. It is a very common custom in dispensaries to give a patient a ticket which lasts for a month. When the month is ended, if the patient is still under treatment, a new ticket is issued, and the patient is counted again. The number of cases treated is also increased (on paper) by other means. The object of these practices is twofold. The public is appealed to with additional force by these deftly manipulated statistics; for to say that '20,000 poor sufferers have been substantially relieved' is more emphatic than to speak of only 10,000. Again, the charities of the city receive pecuniary aid from the city in proportion to the amount of work done; and the more patients, the more money."

"Brevity is the soul of wit" says Polonius, and it would appear that it must also be the essence of modern popular science, as imbibed by amateurs in the healing art. Did many of our readers ever essay to deliver a course of lectures in accordance with the Syllabus of Instruction laid down by the St. John Ambulance Association? If so, the chief difficulty which has confronted them must surely have been the intense compression and condensation of important subjects demanded from the lecturer, if he is to do more than merely allude, in the boldest manner, to the various headings of his text. The course no doubt aims chiefly at practical instruction, but if lectures are to be a feature of it at all, it seems a pity that time should not be allowed, by increasing the number of lectures, for placing the varied subjects in an attractive and coherent, as well as an utilitarian shape. How, for instance, to take one lecture of the prescribed course as an example, can any idea be conveyed, in one hour, of the nature and rational treatment (even such as can be described as "first aid") of such a collection of pathological conditions as the following:—*Collapse, concussion and compression of brain, apoplexy, inebriation, epilepsy, fainting, bites by rabid animals, drowning, suffocation, burns, scalds, poisons.* A moment's reflection would seem to show the utter impractibility of conveying instruction, in a form to be assimilated and reproduced, on one half of the above subjects in twice the time. Lecturers should bear in mind how the (to them) most familiar phrases and words are foreign to the unused ear of the laity. Every word should be English, or if not English, should be written down and explained before the class. We should not then see a great truth disguised as follows:—(a fact) "Bleeding from the nose is neither *Artillery* nor *Venus*, it is *Caterpillary.*"

The *Midland Medical Miscellany*, which is nothing if not didactic, contains a note under the above heading, in which the medical man is exhorted, for the sake of himself, his horse, and his groom, to the observance of Sunday as a day of rest, "urgent, severe, and acute cases," only being attended to on that day. This exhortation, excellent and well-intentioned as no doubt it is, will, we fear, fall fruitless upon the ear of the busy practitioner, to whom release from the routine of professional work, on each seventh day, sounds as the echo of an utopian dream, towards the attainment of which he has long relinquished his ineffectual struggles.

The fact is that it is to the public, and not to the profession, that the homily should be addressed—to the public, at whose summons the medical man must abandon all dreams of rest or relaxation, on the Sunday as on all other days, and who regard the doctor's wishes or convenience with an indifference but little less than that with which the horse and groom aforesaid are considered. Is it not a fact, we would ask the *Midland Medical Miscellany*, and the profession in town and country, that a large proportion of our clients, especially among those classes who lead a busy life during the week, purposely select Sunday as a convenient opportunity for invoking the doctor's consideration of slight ailments, which are deemed too trivial for discussion during time which may, on other days, be more profitably employed? We think that most medical men would testify to the fact, that a rather larger percentage of "fresh calls," and not by any means always to cases "acute, urgent or severe," are received on Sunday than on any other day of the seven. We thoroughly agree with the sentiments of our contemporary; hoping merely that he may find an occasion of insisting upon them to those classes upon whom, not upon us, the responsibility of the doctor's Sunday work must mainly rest.

We are glad to notice the extension of the provident system of medical relief in the provinces. The managers of the Salisbury Provident Dispensary, which has hitherto had a very successful career, and last year received close upon a 1,000*l.* from nearly 7,000 provident members, have determined to extend their operations to the whole of South Wiltshire. Dr. Roberts the honorary physician, who appears to be the leading spirit of the institution, proposed the extension at a recent meeting, in a speech in which he showed a thorough grasp of the principles on which alone the provident system can achieve success. We shall look forward with interest to the future of the South Wilts provident dispensary, for if the ill-paid agricultural labourers in that county can afford to pay for their medical attendance, and can appreciate the advantages of providence, the system should surely prove to be more workable amongst the better-paid London workmen than it has hitherto been. It has worked with success for many years in some of the country districts

in Devon and Cornwall, the miners about Tavistock willingly paying at the rate of 10*s.* yearly, in advance, for medical attendance on themselves and families. In Plymouth, we regret to hear, this system has not been so successful, for though the provident dispensary there has been established for fifteen years, and many of the medical men in the town have been connected with it, the working classes show some reluctance in joining. This is attributed to the neglect of the authorities to conciliate the Friendly Societies, whose proposal to join the dispensary some years since was unwisely rejected.

The drainage of Ramsgate is decidedly a matter of more than local importance. To the inhabitants of the South-Eastern Districts of England and to the many thousand Londoners who yearly resort to what is, perhaps, the most healthy and invigorating spot in the whole country, it is of the highest interest that its sanitary arrangements should be above suspicion. And yet the problem of satisfactorily disposing of the sewage of Ramsgate is one of the most difficult that a sanitary engineer could well have to solve. The curious oscillation of the currents on the coast caused by the meeting of the Channel and North Sea tides renders it almost impossible to send the sewage well out to sea. Every plan for simply discharging unsophisticated excrement on to the shore is open to the objection that the well-known Ramsgate Sands, and the mud in its much frequented harbour, will infallibly be dangerously polluted by it. It is obvious that the only satisfactory plan would be either to convey the sewage to the North Foreland and there discharge it—a scheme which is open to many objections—or to treat it in depositing or clarifying tanks in such a way that when discharged the affluent should be more or less innocuous.

Successive Local Boards at Ramsgate have been fully alive to the importance and the difficulty of satisfactorily solving the problem, and many are the schemes that have been successively proposed and rejected. At length, the Local Board, after many years' hesitation, have in hot haste adopted a scheme, which appears to be about the worst they could have selected. We have before us an elaborate pamphlet by Mr. H. J. Johnstone, formerly Surgeon to St. George's Hospital, who has for many years devoted himself to the study of the problem, and we think he proves to demonstration that the scheme accepted by the authorities would fatally injure the health and reputation of Ramsgate. The main objections to the scheme appear to be that it involves the construction of a large tank sewer, in which the sewage would be ponded up for a certain number of hours under the most frequented part of Ramsgate, and that its contents would be discharged unchanged in such a way that a large portion would inevitably be deposited on the foreshore. There are other serious objections on which we have not space to dwell, but we hope that the whole subject will be carefully considered by the Local Government Board before it is permitted to be carried out.

With an astute recognition of the growing international character of medical science and literature, the management of the *Annales des Maladies de l'Oreille, du Larynx, &c.*, have determined to publish articles in English as well as French, and have secured the services of Dr. Morell Mackenzie, as editor of the new department. Dr. Mackenzie himself starts off in the current number with an admirable article on hypertrophy of the mucous membrane of the nose, extracted from the forthcoming volume of his work on diseases of the throat and nose. The subject is one to which very little attention has hitherto been paid by English practitioners, and many cases must go to their graves without any very exact diagnosis ever having been made. Dr. Mackenzie describes the diagnosis from polypus as easy—to those who can use the rhinoscope.

Under the head of treatment, he recommends the mildest measures in the earlier stage of disease, and though he fully describes the more active measures required in more obstinate cases, thinks it necessary to add a word of caution as to their employment: "For though," he says, "the introduction of the electric cautery and the wire ecraseur permits some relaxation of the rule under which surgeons were taught to 'cut through everything soft, to saw through everything hard, and to tie everything that bleeds,' the spirit of this simple instruction has, I fear, in recent years, sometimes influenced the young practitioner, and the nasal passages have occasionally been 'cleared' with a zeal and energy worthy of the industrious backwoodsman. In several cases that have come under my own care, in which severe measures had previously been urgently advised by others, I have succeeded in affecting a cure by the simple removal of all causes of irritation, and the persevering use of gentle dilatation. I would also warn some of my younger *confrères* that as the appearance of the interior of the nose varies in healthy persons just as much as its outward configuration, it is unnecessary, where no inconvenience is felt, to restore geometrical symmetry to the turbinated bodies, or to invest the lining membrane of the nose with artistic merit. But whilst deprecating unnecessary aggression in this tender region, I do not deny that there are many cases which can only be cured by active treatment."

The January number of *Brain* opens with an important article by Professor Grasset on the relations of hysteria to the tubercular diathesis. The writer endeavours to show that hysteria, like tubercular meningitis, is but one of the evidences of the tubercular diathesis. "In a phthisical family, you will see among the children of a tubercular subject, one dying of tubercular meningitis, another become an ordinary consumptive, while the third seems to escape the diathesis. The last may be neurotic, hypochondriac, hysterical, lunatic even; but for once he has escaped the hereditary diathesis in appearance only. He is tubercular, like the rest, though he has no tubercles anywhere. It is his neurosis which is the manifestation of his diathesic affection. And what proves it is, that in his children the diathesis is still present, and will often resume its classical type. Son and father of phthisical subjects, he does not interrupt the diathesic chain; only pulmonary phthisis is in him replaced by

hysteria. Moreover, he may prove the nature of his neurosis by becoming himself phthisical in the second portion of his life; and then there are often most remarkable phenomena of alternation and equilibration between the two manifestations of the same diathesis." This important thesis is sustained by records of numerous cases, which are analysed with care. The published article is the first instalment only of the whole paper, and we refrain from comment until the evidence is complete. In the interim we must say that the case is ably presented, and deserving of careful examination.

Dr. Buzzard contributes a case of posterior spinal sclerosis, which is completed by a microscopical examination of the cord, and is important from the fact that the morbid change is shown to have begun in the walls of the blood-vessels, and to have spread from thence to the neuroglia, and so to have affected the nerve-tissue proper. The accepted view of the origin of the change in tabes dorsalis is that it begins in the nerve-tissue and spreads secondly to the neuroglia. An excellent critical digest of the complicated subject of the innervation of the heart is given by Dr. Byrom Bramwell, forming a compendium of all that is at present known of the matter. The reviews are numerous, and are characterised, at least in two cases, by a severity which is unusual, but which is thoroughly deserved.

On Saturday last, Dr. Bayley Balfour, Professor of Botany at Glasgow, was elected from a large field of candidates to the Botanical Chair at Oxford; and on Monday his father, Dr. J. H. Balfour, died, after long years of faithful service in the corresponding Chair at Edinburgh. Dr. J. H. Balfour was born in 1808, and took his M.D. degree at Edinburgh in 1831. Ten years later he was appointed to the Chair of Botany at Glasgow, which his son has just resigned. Recalled to his alma mater, he held for many years the professorship of Medicine and Botany, and the directorship of the Edinburgh Botanical Gardens. During the last eight years of his occupancy of the Botany Chair he was assisted by his son. He was a Fellow of the Royal Society, and of many foreign academies, and the author of many books, still popular with amateur botanists, and of articles of a higher order—notably the article "Botany" in the *Encyclopædia Britannica*.

His son, Dr. Bayley Balfour, was educated at Edinburgh, and took his D.Sc. with high honours in botany, in 1875, and his M.B. and C.M. also with honours two years later. In 1874, he was appointed naturalist to the Government Transit of Venus Expedition to Rodriguez, and the results of his researches appeared in the *Philosophical Transactions*. In 1879, he was appointed Regius professor of Botany, and superintendent of the Botanic Garden and Herbarium at Glasgow. In 1880, he made a scientific survey of a spot especially dear to the medical student — the island of Socotra — the full details of his researches there being still in process of preparation. He will find his berth at Oxford a pleasant and not too onerous one. A Magdalen fellowship and a residence in the Botanic Gardens opposite are attached to the professorship, the emoluments of which amount to 700*l.* a-year.

Mr. Thomas Duxbury writes to us in connection with the Blackburn vaccination enquiry, on which we had a note last week, asking our readers to suspend their judgments for the present, as an additional enquiry has been asked for. Mr. Duxbury complains of the inaccuracy of many of Dr. Page's statements. It is not true, he tells us, that he is the secretary of the Blackburn Anti-vaccination Society, nor is it true that he never saw the deceased child. Further, one all-important witness refuses to corroborate the statements she made to Dr. Page. It seems to us that unless Mr. Duxbury can bring forward more important evidence of inaccuracy on the part of Dr. Page than is contained in his letter, there is not the slightest justification for re-opening the enquiry. The evidence on which Dr. Page formed his opinion, is probably of such a kind that Mr. Duxbury is entirely incompetent to appreciate. Mr. Duxbury does not bring forward a tittle of evidence to show that the vaccination had any evil results, for mere unreadiness on the part of the vesicles to heal means nothing in the absence of other definite pathological evidence.

According to the report recently issued the whole number of students in attendance during the last year, in the Harvard University Medical School, amounted to 240, and of those, 116 had a literary or scientific degree. There were 85 applicants for the degree of Doctor of Medicine, and of these, nine were rejected. 70 received the degree of M.D., after a three years' course of study, and six after four years; and, of these six, four received in addition the degree of A.M., two of them *cum laude*.

THE DEBATES ON CHOLERA AT THE EPIDEMIOLOGICAL SOCIETY.

The adjourned debate at the Epidemiological Society on Surgeon-General, or, as we must now call him, Sir William Hunter's report on the Cholera in Egypt, on Wednesday, went off rather slowly; for, owing to most of the speakers having exceeded the ten minutes, to which they should have been restricted, only seven of the thirteen who had sent in their names could be heard, and these, unfortunately, almost without an exception, represented one section, viz., that of the so-called "anti-contagionists," or those who deny, more or less explicitly, the propagation of the disease by human intercourse, attributing its origin and spread to local, climatic, and meteorological conditions, without the intervention of any material entity—call it germ, or poison, or what you will.

Setting aside the opinions of such extreme partisans as Inspector-General Lawson, who, as our readers may remember, ignoring entirely the results of recent microzoic pathology, denied in a communication to our pages last July, that there was any evidence of the existence of a material entity passing from one indi-

vidual to another in small-pox or scarlatina (though he did not reply to our question as to vaccination !) we may venture to express our belief that the dispute is, as regards most, a battle of words. We can only explain the strange divergence of opinion among many who have had equal experience, and, we may assume, possess equal judgment, as the result of a blind adhesion to the crude conceptions of a bygone pathology, preserved in the popular notion of contagion, which they have failed to modify with the progress of scientific observation and research. We freely admit that cholera is not contagious in the same sense as small-pox, measles, and scarlatina are—that is, communicated independently of all external conditions whatever from one individual to another by the direct passage from one to the other of some poison probably, if not certainly, material and living ; but we believe that there is evidence, irresistible, though as yet circumstantial only, that a specific and presumably similar entity constitutes the essence of cholera, though the mode of its propagation be somewhat different—that is, that instead of being immediate and independent of external conditions, it requires the concurrence of various factors collectively known as sanitary surroundings and meteorological or climatic conditions, and probably also a certain modification or development of the poison out of the body.

Call it a miasm, if you will, from its dependence on local circumstances the fact of its being epidemic and not solely endemic shows that it is not like the miasmata proper, the malarias rooted to the soil. In some way or other it is transportable, a fact that does not militate against its local origin, for both characters are presented unequivocally by yellow fever, and, though less conspicuously, by enteric. Dr. Thrupp, whose remarks were by far the most lucid and logical, expressed his belief that the true solution of the problem should be sought, and would be found in a study of the pathological and clinical relations of epidemic cholera, and the forms of disease known as cholera nostras, sporadic cholera, choleraic diarrhœa, &c. To a certain extent we agree with him, but we venture to deny, or rather we deny most positively, that there is no difference beyond that of degree between true cholera, mild or malignant, and the cases of acute, often fatal, diarrhœa observed everywhere in the months of autumn. Many of these present all the symptoms of genuine cholera—cramps, rice water evacuations, suppression of urine, and depression of temperature, but only the followers of Hahnemann, we think, would hold that a set of symptoms *per se*, however marked, constitute a disease. Scarlatina is not tonsillitis, or even tonsillitis plus erythema, though when these are present together, as we have seen them, diagnosis may be by no means easy.

Several of the speakers ridiculed the test of propagation or communication of the disease, but granting the specialty of cholera, and to deny it, is to be the question at issue, we do not deem it illogical. Scarlatina, to appeal again to analogy, may exist, as verified by its communication in an unequivocal form, almost without any of its characteristic symptoms, and the symptoms to all appearance may co-exist without the disease. The symptoms of real cholera may be induced by arsenical poisoning, as Dr. Longhurst remarked, and by an excessive dose of Epsom salts, but no one would assert that they constituted the case one of cholera. Precisely so ; the symptoms of cholera may be produced by the ordinary causes of autumnal diarrhœa in the absence of any specific poison, and the cases, however numerous, remain still personal, not epidemic. On the other hand, we have cholera without any of the palpable and characteristic symptoms, either because recovery set in at an early stage, or because the very intensity of the poison killed the patient before the symptoms had time to manifest themselves.

Whether the cause of cholera be in the air above, the earth below, or in the water under the earth, its transmissibility or transportability is evident to every one who has not a preconceived theory to maintain, but transportability is not contagion in the stricter sense of the word. It is intimately connected, as regards its origin and perpetuation with local conditions, but it is, though so far miasmatic, not endemic in the same sense as malaria which is rooted to the spot of its birth ; yet constant presence in a place is not in itself endemicity, or, as Dr. Murray humorously remarks, syphilis must be accounted endemic in London.

In the face of all these facts we are driven to accept one or other of the hypotheses advanced by Pettenkofer and Hirsch. The former believing that the poison generated outside of, and independently of, the body is carried by persons, infected or not, by clothing, merchandise, and ships, until finding circumstances favourable to its multiplication, it sets up an epidemic ; and the latter, that the poison when first eliminated from the human body, is devoid of or possesses, but feeble power of infection, for the acquisition of which a certain development or modification amid favourable conditions is requisite. The latter view is in our opinion supported by a large mass of evidence, such as the comparative immunity enjoyed by the attendants on the sick in well-conducted hospitals, but not in the confined dwellings of the poor. The severity with which the disease affects a population amid bad sanitary surroundings, and especially where the water is polluted, and on board crowded and confined emigrant and pilgrim ships, compared with its lightness when introduced when the opposite conditions, especially as regards the water, prevail—so strikingly illustrated by the successive epidemics in London. And lastly, the success attained by Dr. Burdon Sanderson, in the infection of mice with stale choleraic fæces, the virulence of which rose and declined between the second and fifth days, with the failure of all attempts at direct inoculation, although we admit that such experiments require repetition and verification.

In conclusion, we may state our belief that the apparently spontaneous outbreaks of cholera, without recent importation occurring, as all well authenticated instances have in the years immediately following epidemics, are easily explicable on the perfectly justifiable hypothesis of the poison remaining dormant in the soil ready to wake up to fresh activity on the return of the required favourable conditions of hot weather, &c., or as in Indian camping grounds, on the arrival of susceptible individuals on the infected site.

THE LASH.

It is well known that the judges differ very materially in the views they take of flogging as a punishment, and, as might be expected, these differences of opinion find expression in the sentences they inflict. The addition of flogging to a term of imprisonment, or penal servitude, in cases of robbery with violence, is in the option of the judge; and so, while some of the present occupants of the judicial Bench lose no opportunity of inflicting the cat, others never, under any circumstances, resort to it. An element of caprice, or personal idiosyncrasy, is thus introduced into the administration of justice, which is much to be regretted, and which must go far to neutralise any deterrent influence that flogging may possess. The most striking characteristic of the criminal class is their want of forethought; in nine cases out of ten, the possible consequences of any unlawful act which they may be about to commit never enter into their calculation. But flogging is intended to be a powerful appeal to their terrified imaginations; the hope being, that a vision of the triangles and the fierce-knotted cords will rise up before them when they are on the verge of a robbery, and will either drive them back, or induce them to deal tenderly with their victim. And this being so, it is clear that there should be no doubt about the certainty of the retributive cat, in case of detection, for the "vision of judgment" becomes instantly faint, distant, and ineffectual, if there is room for speculation as to the chances, should the worst come to the worst, of falling into the hands of a kind-hearted old judge, who cannot bear to think of a scored and bleeding back. Under existing circumstances, the lash does not always fall on those who most deserve it, and to whom it is likely to prove most useful; and it seems clear, that flogging should either be abolished, or inflicted with strict uniformity and impartiality on all who have, by their criminal proceedings, brought themselves within range of it.

Mr. Justice Day is certainly of that judicial section that favours the cat, and seems indeed to be ambitious to distinguish himself as a flogging judge. He has expressed his intention to order corporal correction in all cases brought before him, in which violence has been added to robbery, and certainly no exception can be taken to his exercise of those powers entrusted to him by the Legislature for the punishment of evil doers. As long as flogging is allowed, he is entitled to order it, although, perhaps, when he has had more experience as a judge than he has as yet enjoyed, he will modify his sanguine estimate of the value of this drastic remedy. But while indulging his partiality for flogging, Mr. Justice Day ought to do so in a way that is not likely to offend the public taste and create sympathy for the convict—as a sentence, such as that which he passed at Leeds on the 2nd instant, is, we fear, well calculated to do. He then ordered James Marshall, who had been convicted of robbery with violence, to be imprisoned for fifteen months, and during that time to be twice flogged; receiving each time twenty-five lashes. We have no doubt that Marshall richly deserved punishment, and had he been ordered to be flogged once for all we should not have had a word to say about his case, but the division of his corporal punishment into two lots seems to us a refinement of severity, which, although legal, is not expedient. It is to be remarked that no dates are fixed for the infliction of the floggings, which may be administered at such times as are deemed expedient by the officers of the prison, who have thus a very large discretion left in their hands as to the amount of suffering they may inflict on this man. If his floggings be administered to him promptly, and in quick succession, he will have to endure only one tithe of the anxiety and misery which will fall to his lot if one or both of them be kept hanging over his head till near the end of his term of incarceration. A prisoner has no notice of the time when he is to be flogged, until he is suddenly called out of his cell and told to strip, and it is an established fact that the mental agitation and forebodings of pain, which they suffer while awaiting flogging after having been condemned to it, has a serious effect on their health. They lose weight rapidly, and become anæmic and nervous, and thus the man who is kept for months in daily apprehension might have his health seriously and permanently impaired. We do not suspect our prison officials of cruelty or unnecessary severity, but it is an indisputable fact that the nature of their duties has a tendency towards mechanical routine and stern repression. Not much sentiment is to be found in a prison governor, and as for an old warder, he is the very type of automatic discipline, and has come to regard the miserable beings under his charge almost as his natural enemies. Such men are not likely to shrink from making punishment as sharp as possible, and it is conceivable, therefore, that a prisoner sentenced to two floggings, and left in their hands, might fare very badly. Twenty-five lashes administered, not by a drummer-boy, but a stalwart warder, who is on his metal to show to his critical colleagues around how thoroughly and scientifically he can perform his duty, is an excruciating punishment that may leave its marks on a weakly man for the rest of his days; but it is a punishment the effects of which must, in great measure, depend on the condition of its recipient. If he be in sound bodily health, its effects will be trifling to what they will be when his blood is impoverished and his nervous system unstrung. But prisoners under sentences of imprisonment for terms less than two years are very differently fed from convicts under sentence of penal servitude, and on the bare-subsistence dietary to which they are restricted they run down rapidly in constitutional vigour, even when no loss of weight marks their decline. If, therefore, a prisoner condemned, like Marshall at Leeds, to fifteen months' imprisonment be flogged at once, that infliction will have a trivial effect on his health, compared to what it will have if it be held in reserve until he has been reduced by low diet, solitary confinement, and hard labour. We confess to a strong dislike of repeated floggings, as being vindictive in their nature, and an elaboration of suffering, savouring more of the Spanish Inquisition than of an English court of justice, but if they are to be allowed, the judge ordering them ought to be required to specify the date of infliction of each flogging. If we remember aright, Lord (then Mr.) Justice Lush, the great flogging judge of the

garotting era, never ordered repeated floggings; he was content to order one immediate and sharp infliction.

The whole question of flogging in prisons deserves more attention from the public than it has hitherto received. An immense number of chastisements are administered every year in English prisons for prison offences, by order of magistrates or the directors of convict prisons. Magistrates are apt to have a leaning to the cat-o'-nine tails. Those aristocrats amongst them who have been "swished" at Eton, and the upstarts who only wish they had, are alike inclined to attach much efficacy to direct appeals *ad cutem hominis*. Dressed up in a little brief authority, it gratifies them to play such tricks as make the prisoners tremble, and so they flog, we venture to assert, oftener than is necessary for sound discipline, and in cases where the lash is not likely to do any good. We have heard of cases in which objectionable prisoners, whom medical officers have declared unfit for corporal punishment, have been put on extra diet and brought up to a point at which it was deemed feasible to submit them to such correction, which was then forthwith administered. Prisons have high walls and are conducted *in camera*. The wretched beings who pass through them, have neither the wit nor the will to complain of any harshness or severity that may have been visited on them while they were in durance vile, and if they did tell the secrets of their prison-house, it is certain that their revelations would not meet with much credence. We do not suggest that such abuses as were disclosed in "Never too late to mend," are now possible in English prisons, on the contrary, we believe that these establishments, are, as a rule, conducted in a humane and praiseworthy manner, but like all other human institutions, they are liable to lapse into evil ways, and they may indeed be regarded as having a special liability to degenerate, because they are removed to a great extent from the invigorating influence of public opinion. Most true is it, as Mr. Herbert Spencer has observed, that as regards all administrations, public and private, it is our duty to assume, not as people usually do, that things are going right until it is proved that they are going wrong, but that they are going wrong until it is proved they are going right. People are taught, and it is to be presumed believe, that the heart of man is deceitful above all things, and desperately wicked, and yet strangely enough believing this, they place implicit trust in those whom they appoint to any functions. Without taking the worst view of human nature, it must still be maintained that it will not go straight without being watched, and it is unfortunate, therefore, that prisons which are so circumstanced as to have special tendencies to diverge from the path of rectitude, should be so much removed from public vigilance. The facts just brought to light at the inquest on the body of David Ackroyd, at Hull, must awaken the public to the truth, that an appalling state of matters may exist in an institution which is supposed to be moving on smoothly enough, and must convince them that prisons cannot be safely left to the management and supervision either of magistrates or government officials. The healthy invigorating light of publicity, must somehow be made to shine in on them more than it has hitherto done. Coroner's juries cannot too strictly discharge their duties in inquiring into the treatment of prisoners who die, and the Howard Association would do well to advise the public on the question of flogging in prisons.

CLINICAL PAPERS.

No. VI.—Convulsions, "Neuromimetic" and Epileptic.

The frequent use or misuse of the term *neuromimesis* is important enough to merit a little reflection, owing to its obviously practical bearing. As introduced by its coiner, Sir James Paget, the word was rich in suggestion and irreproachable in meaning; but being now, perhaps naturally, but too often, misunderstood by the unclassical or the thoughtless practitioner, its effect on medical terminology is far from being wholly luminous. Applied as this term is to cases commonly called Hysterical, the "mimicry of disease" expressed in it is frequently attributed as a more or less conscious act to the subject of the affection, rather than to the affection itself. Hereby the pathological aspect of the malady is obscured rather than enlightened, and the perverted use of this name, good in itself, has tended frequently to cause both diagnostic error and faulty treatment by emphasizing or favouring the notion that Hysteria and Shamming are mainly identical. On the falsity of this notion it is unnecessary now to insist; though still of undue prominence in the minds of some practitioners, it is gradually and surely dying out in the light of better observation and a more rational psychology. An element of conscious shamming there may undoubtedly be in some patients who are properly called hysterical—even as there is often an element of true hysteria in the symptoms of patients suffering from structural organic disease—and this element it is often difficult to duly assess; it is true enough too that unmitigated impostors may be found in Hospital wards, as in many other less pleasant places. But it is no less true that in a large number of cases which may well be called hysterical or "neuromimetic," there is no ingredient of deception whatever. It is especially in those cases, from time to time coming before practitioners, of convulsions, chiefly in women, the nature of which it is necessary to approximately decide—whether they are epileptic or hysterical—that the danger is great of confusion of neuromimesis with the old notion of shamming in Hysteria. Leaving alone all question of the ultimate pathology of Hysteria and Epilepsy in their convulsive expressions, it may be taken for granted that while on the one hand there is often a broad clinical distinction between them, obvious, indeed, to even an unskilled observer, yet on the other hand, it is sometimes a matter of great difficulty to give a case of convulsions its right name, with due regard to the practical outcome of the opinion. Such cases as these are to be looked upon perhaps as on the border-line between Epilepsy and Hysteria, or, in other words, the fundamental pathology of the two affections may not be so very dissimilar. The question of unconsciousness and insensibility to pain seems to be the great "crux" in the matter of diagnosis here; it is, indeed, a difficult, sometimes an unanswerable, question

in the investigation of nervous disease, the evidence being mainly of what is called a subjective nature. But when the body's expression of these sensory symptoms is indefinite, it is well to avoid undue dogmatism in forming our opinion. Whenever in the mind of a practitioner the notion of malingering is implied in the diagnosis of Hysteria, the importance of bearing in mind the difficulty of these cases is very obvious: for prognosis and treatment are herein gravely involved. However subtly the cases obviously hysterical may be linked together with those which are called epileptic, these well marked cases at the opposite ends of the chain have very different clinical results, and call often for widely separate treatment.

No better example of what has been said can be given than those not altogether uncommon cases where self-inflicted wounds occur in connection with "fits." Doubtless there are plenty of recorded instances where there is good reason to believe that women, and girls especially, who have *bonâ fide* hysterical convulsions, have with or without some power of control inflicted wounds upon themselves, with or without some obvious motive. But it is important that all such cases should not be put down as "neuromimetic," with a reserve theory that the patients are shamming or desirous of becoming "interesting" or "good cases." For it is equally well known that genuine epileptics—patients who have had fits from childhood, and of whose unconsciousness during the fits there can be no reasonable doubt—have often periods in the intervals of their fits, though most often immediately succeeding them, when their actions are of the strangest kind, and when they frequently inflict injury on themselves or others. Such cases of strangeness, in varying degree and combination with obviously convulsive attacks, are known under the title of epileptic vertigo, and some may pass into "epileptic insanity." Homicide, beyond doubt, is sometimes committed in this condition: of which in all probability the apparently motiveless act of one Treadaway, who after trial was sent to Broadmoor some years ago, was a striking example. Disordered sensation is an incident in epilepsy, and well known in certain forms of insanity; and in these facts may be found the clue to the explanation of many cases of wounds self-inflicted by patients subject to fits. From neglect of due observation and thought, therefore, a case of genuine epilepsy, with the accompaniment of obviously self-inflicted wounds, may be regarded as an example of a feigned disease due to "Neuromimesis"; the perverted use of this term being intimately bound up with the faulty diagnosis. It should never be lightly concluded that people, even women, will inflict pain and disfigurement on themselves with no other morbid motive or cause than a simple desire to attract attention, though this is doubtless sometimes the case. There is nearly always something morbid to start with in the nervous constitution of an individual who thus behaves.

The bearing of these considerations is of no less importance on treatment than on diagnosis. While the epileptic convulsion, and many of its sequent phenomena, are greatly controlled by the administration of the bromides, it is, to say the least, very doubtful whether the hysterical condition is at all benefited by them. If it be indeed advisable in some extreme cases to prescribe such drugs to an hysterical patient, it is almost beyond question that in the long run her condition will be aggravated by the continuance of such treatment; while, on the other hand, to treat a genuinely epileptic patient as a neuromimetic, and possibly, by implication, as a malingerer, would be a blunder of the greatest magnitude.

Σ

REVIEWS AND NOTICES OF BOOKS.

THE LITERATURE OF THERAPEUTIC NOVELTIES.[1]

SIDE by side with the growth of scepticism in the profession as to the power of drugs to cut short or seriously modify profound disease-processes, there has arisen a widespread credulity with respect to their power of mitigating symptoms and relieving minor sufferings. The typical general practitioner and those amongst the consultants who approach him in tone of mind, are ever on the watch for what, in the absence of a better name, are commonly termed therapeutic "tips"; they are anxious to startle and compel the confidence of their patients by an undeniable proof of their skill, and they are desirous of flattering themselves into the belief that they are keeping well abreast of the science of the day, by prescribing the most recently discovered drugs. There is no portion of the medical journals so eagerly scanned as that in which the promise is held out of treating old and obstinate complaints by new methods; and in answer to a similar demand, there has arisen quite a literature of new remedies, from which we have selected a few examples for review.

It is now sixteen years since the last edition of the British Pharmacopœia appeared, and in the interval an altogether appalling number of therapeutic agents have come forward as candidates for admission into that select society, a place in which it is as difficult to obtain as it is easy to retain when once gained. Of the newer remedies some—such as salicylate of sodium, croton chloral, pilocarpine, iodoform, eucalyptol, chrysophanic acid and vaseline—will of course find an easy entrance into the forthcoming edition of the Pharmacopœia; but in the case of the countless remedies now being introduced and highly lauded by American wholesale houses, a very searching examination will be necessary before any of them are admitted. Most of them may well wait another fifteen or twenty years, by which

[1] (1.) "The Extra Pharmacopœia of Unofficial Drugs," by W. Martindale, F.C.S., and W. Wynn Westcott, M.B. London. Second Edition. London: H. K. Lewis, 1884.
(2.) "The Year-Book of Pharmacy, with the Transactions of the British Pharmaceutical Conference, for 1883." London: J. and A. Churchill, 1883.
(3.) "A Compendium of Modern Pharmacy," by W. B. Kilner, Pharmacist. Fifth Edition. London: H. Kimpton.
(4.) "The Medical Annual and Practitioner's Index," 1883-4, London: H. Kimpton.
(5.) "The Newer Materia Medica; designed and issued to the Medical Profession," by Parke, Davis, and Co., Detroit, Michigan, U.S.A.
(6.) "Klinisches Recept-Taschenbuch für praktische Aerzte." Vienna: Urban and Schwarzenberg.

time it may be expected that the large majority will have been entirely forgotten. Ever since Shakespeare's courtier lauded parmaceti as "the sovereign'st thing on earth" for an inward bruise, and even earlier, it has been the way of drugs to come in with a flourish of trumpets as specific remedies, and then to be relegated in disgust to a back shelf when their imposture was discovered. Albert Smith's lines—

> "K stands for kreosote, much overrated;
> L for the lies that about it were stated;"

could be applied to a score of remedies, and the same process will happen with hundreds more, so that the practitioner who is wise will rather trust to his old friends, and leave the new candidates for his favour alone until they have been tried and have succeeded in the hands of more adventurous therapeutists.

For those, however, who are anxious to help in the testing process—in which case they should make up their minds to keep careful records of their successes and failures, especially the latter, and to publish them with a view to economy of labour—there is provided a literature from which they can gain what they want without the trouble of turning over volumes of medical periodicals. The best specimen of this literature that has come into our hands is Martindale and Westcott's "Extra-Pharmacopœia," the first edition of which appeared last summer, and was exhausted in a few weeks. It has evidently been compiled with great care, the references to contemporary English medical literature are singularly complete, and the pharmaceutical part is well done. The remarks on the comparative merits of the vaseline class, and on the art and science of pill-making are especially worth reading. For the "tip"-hunter there is added a list of diseases with appropriate remedies, and the practitioner's only difficulty will be to select from the crowd of drugs the one which he deems most worthy of his confidence, or rather, least worthy of his distrust. We are sorry to see that here and there the book shows a taint of the homœopathic heresy—v. *Anthoxanthum*, but in this it only follows the bad example set by certain more ambitious treatises.

"The Year-Book of Pharmacy," which is not so well known to the profession as it deserves, still keeps up its high reputation as the best annual summary of progress in materia medica and pharmaceutical chemistry. It is true that the profession has less reason now than it once had to busy itself with pure pharmacy; but if it be true, as Prof. Attfield stated in his address to the Pharmaceutical Conference, that one effect of the hard times of the last ten years has been to increase the proportion of medical practitioners who dispense their own medicines, the time has not quite come for the devolution of the whole science of pharmacy to the druggists. There are many medical men in the country who would find the "Year-Book of Pharmacy" a very useful companion; while the lecturer in therapeutics and materia medica would gather much necessary information from its pages. One of its most useful features is very complete bibliography.

Kilner's "Modern Pharmacy," an American production, is written chiefly for the use of the pharmaceutical chemist, but the author informs us that it has also been his aim "to place before the busy practitioner information which can alone be found in the private working formulæ of the practical chemist, or in the huge costly volumes of authors whose prolific (*sic*) pages one has to hunt through, in order to arrive at the knowledge of which they profess to be the vehicles." The book contains many hundred formulæ, not only for drugs, but for toilet requisites, fly poisons, incense powders and other nostrums, which the respectable practitioner is not usually called upon either to prescribe or dispense. It also professes to give the formulæ of all the better-known patent and secret medicines. As for any hints for treatment that it contains, it does not pretend to meet other demands than those of the counter prescriber.

The "Medical Annual," we must confess, is rather out of place in the present company. Its aim, apparently, is to be a medical "Whitaker," and if it had been more carefully compiled it would serve a more or less valuable purpose. It contains much information that will be found of use to the practitioner, notably a gazetteer of health resorts and of the more important towns in the United Kingdom. A large portion of the volume is taken up with "brief notes of the principal facts and hints which have appeared in the medical journals during the year," and with particulars of new remedies. The former section is a fairly good *resumé* of the therapeutical work of the year, and professes to have been compiled from a very long list of British and foreign journals. It will, no doubt, be appreciated by the hard-worked practitioner who has little time to study the literature of his profession. Unfortunately it teems with printer's errors.

Under the pretentious title of the "Newer Materia Medica," Messrs. Parke, Davis and Co., have issued a wonderfully elaborate volume, in which seventeen of the newest remedies are exhaustively described and illustrated, with copious extracts from medical literature as to their therapeutic properties. It is a curious commentary on the drug-loving nature of humanity, that it should be worth the while and within the means of a wholesale house to issue such a costly circular. The drugs treated have all a certain claim to consideration, and most of them appear to have been tried very conscientiously, if we may judge from the number of diseases in which their results are described. It goes without saying that several of them are declared to be useful in dysmenorrhæa.

The "Klinisches Recept-Taschenbuch" is a little volume with which we have been familiar for some years, and we have not seen a very recent edition of it. It does not profess, however, to have anything to do with the newer remedies, but under each disease gives an outline of the accepted treatment, and a short list of the formulæ which have been found useful in it. It is the last book that we should place in the hands of the student; but by the practitioner, familiar with the rational treatment of disease, it will sometimes be found a valuable help in refreshing the memory; and the seeker after "tips" might do worse than consult it. For our own part, we chiefly value it as a means of comparing the treatment of different diseases which prevails in Vienna with that in vogue amongst ourselves.

The Encyclopædic Dictionary; with numerous illustrations. Part I. London: Cassell and Company.—This important literary undertaking of Messrs. Cassell, the first monthly shilling part of which has just appeared, has been so fully and so favourably noticed in the daily press, that only a brief criticism, dealing exclusively with the medical aspect of the work, is necessary here. We have discovered no very important omissions, and it must be admitted that the compilers have shown a very sound judgment in the medical classics chosen to illustrate the meaning of terms. In medical language the change in the exact connotation of words is often so rapid that we should be glad to have seen less use made of Todd and Bowman's "Physiology," which has long been out of date. We have noticed several instances of inaccuracy and careless revision, and we shall probably do the publishers better service by pointing out a few of these than by further expressions of eulogy. Under "Abduction," the quotation from Todd and Bowman refers to the second specific or physiological meaning, and not to the surgical meaning, under which it has inadvertently been placed. The definition of "abductor" as "a muscle which pulls back any part of the frame" is clearly incorrect. The reference to Lord Herbert, of Cherbury, as an authority for the use of the verb "to abort" in the sense of to miscarry is misleading—such use of the word being not at all uncommon in the present day. No medical meaning is given under the word "abrasion," though the schoolmaster, whose examination paper recently created so much merriment, expected to find boys of twelve familiar with such a use of the term. The definition of a diffused abscess as one due to contamination in the blood, is misleading. No medical meaning of the verb "to absorb" is given, though it is constantly used in this sense. "Absorption" by organised bodies is described as "imbibing material suitable for their nourishment," a definition which entirely overlooks the absorption of *poisonous* material, which plays such an important part in the production of disease. Under "Acarus" no mention is made of the itch-insect; and *Achorion Schœnleinii* (*sic*), which occurs a few pages later, shows signs of careless revision. Under "Acetone" it should have been noted that this substance is sometimes found in the blood, even if it were decided that the word "acetonæmia" is too technical for admission into the dictionary. It is curious that no reference is made to the use of the word "acidity" as a dyspeptic symptom, though there is not a single medical word more loved by the laity, and a few columns further on, "Acor," a word we never heard used before, is defined as acidity or sourness in the stomach. *Cochlearia amaracea*, it may be noted, is not the botanical name of the horseradish, and "having the form of a gland" does not convey an accurate notion of the medical use of the word "adenoid." These few examples will, we think, suffice to show that if the encyclopædic dictionary is to merit the confidence of the medical profession, its future parts must be submitted to a more careful and less antiquated revision.

The History of the Year, from October 1, 1882, to September, 30, 1883. London: Cassell and Co., 1883.—This is the second year that this useful summary has appeared, and it still continues to deserve credit for accuracy and readableness. The volume does not contain any account of the medical history of the year, but we are not sure that it is the worse for that. Medical men always know where to go for that, and wise laymen avoid it. The obituary of eminent medical men who had died during the year is concisely and accurately given. One error we have noticed in the section on Egyptian affairs: the first cases of cholera at Damietta appeared on June 22, 1883, and not on June 26, as stated. Those who have had to do with the investigation of this outbreak know that this is not such an unimportant inaccuracy as it may seem.

The Royal Society.—Five eminent foreigners have been elected foreign members, namely, Prof. Anton de Bary, Prof. Carl Gegenbaur, Prof. Leopold Kronecker, Prof. Rudolph Virchow, and Prof. Gustav Wiedemann.

ABSTRACTS AND EXTRACTS.

THE PRESS ON THE VIVISECTION VOTE AT OXFORD.

The *Times* in an article on the recent vote in Convocation at Oxford, declares that all those who are open to argument have been long ago convinced that science cannot proceed on her beneficent way without the aid of experiments, some of which must be painful. Parliament, on the recommendation of one of the strongest Royal Commissions ever appointed, has legislated in the matter, and physiological experiment is now under limitations as severe as it is possible for it to be consistently with any kind of progress in discovery. Abuses are of the rarest occurrence. It is to be hoped that the sensible action of Convocation will not only encourage the Waynflete Professor to proceed as his scientific conscience may guide him, but will convince the well-meaning but irrational opponents of scientific freedom that further action on their part would be not only vexatious, but unsuccessful.

The *Observer* is glad to see that the attempt to impose insulting restrictions on the work of the new professor of physiology at Oxford, has ignominiously failed, notwithstanding the strong whip made by the obstructive party. Referring to Mr. Freeman's argument, it says "Demonstration of known truths is one thing, and discovery of new facts another, and unless Mr. Freeman believes that after letting Retiarius and Secutor perform in the Sheldonian, we might possibly find the lost books of Livy on the floor, there is no conceivable analogy between the two cases."

The writer of an article communicated to the *Guardian* says, "When there is a question, as it seems there will be at Oxford, of putting young men in the way of, and accustoming them to, the practice of inflicting what may be needless pain; when, moreover, it is a question of doing this under the official sanction of the University, in buildings provided by and under a teacher paid by her; and when further the University, as such, has not previously had an opportunity of pronouncing fairly upon the question whether vivisection shall or shall not be tolerated in her schools, it seems to us that those who have promoted the opposition to the proposed expenditure of University funds on such purpose, have acted strictly within their reasonable rights."

The *Spectator* thinks that the issue was one of the most momentous moral issues of the day, and describes the vote as a disaster and a calamity, by which the University has sanctioned the inhuman principle that there is no limit to the anguish which a properly trained physiologist has the right to inflict for what he considers a sufficient object.

Truth says that on the merits of the case there can be no sort of doubt. It would have been monstrous to have elected Dr. Sanderson to the professorship and then to have withheld the money for his laboratory; and as to the objections of the anti-vivisectionists, why is the law of the land insufficient at Oxford.

The *St. James's Gazette* says that the vote is regarded by the scientific party as a victory for "science," and it, at any rate, may be considered a victory for common sense.

The *Pall Mall Gazette* thinks that the Oxford University is to be congratulated on the result of the division, and that Mr. Nicholson and his friends would do well after so decisive a vote, to abandon any further opposition to the establishment of a real school of physiological research at Oxford.

Nature describes the scene in the Sheldonian Theatre as the most exciting that has been enacted in the University since the opposition to Dean Stanley as select preacher. The result was received with enthusiasm, and Oxford is to be congratulated on it.

The *Lancet* thinks that Dr. Acland, by his letter in the *Times*, and by his action in the recent debate in Convocation, has laid the whole scientific world under obligation, and has effectually foiled the attempt to place Oxford in a false position in relation to biological science. The vote of Convocation is the just reward of the stand made by him.

The *British Medical Journal* says that the result is a complete answer to those who have frequently stated that the narrow majority would in any subsequent occasion be turned into a minority.

MEDICINE.

Sudden Death due to Hæmorrhage from the Hepatic Vein.—The *Boston Med. and Surg. Journ.* for Dec. 20, 1883, contains a report by Dr. Alf. F. Holt, of a case in which death appears to have been brought about in an unusual manner. The patient was a large and strongly-built Englishman, æt. 56. Ten or twelve years before his death he began to have severe attacks of colic, which continued to trouble him throughout his life at irregular intervals. For the last six or seven years he had never been quite well, suffering from what had been variously diagnosed as "gall-stones," "dyspepsia," and "obscure liver-disease." Seven days before his death he was suddenly prostrated, while at business, by severe abdominal pain, nausea, vomiting, and faintness; in the evening he vomited rather more than three pints of blood. The pain and sickness, though somewhat relieved by treatment, continued for another three days, when he was again seized with an attack of vomiting, blood, as before, being ejected in the form of very large clots. When nearly two quarts (*sic*) of blood had been ejected, the vomiting suddenly ceased; pain also ceased in about two hours' time, but the patient did not rally, and died in about forty-eight hours, or a little less than seven days from the beginning of the sickness. No blood was at any time passed *per anum*. The most noteworthy points revealed at the necropsy, made twenty-three hours after death, were as follows:—All the tissues contained but little blood; the pericardium was normal, but, on opening it, the right auricle and ventricle were seen to be remarkably distended, and were elastic to the touch; on incising them, a puff of gas escaped, and their walls immediately collapsed. The left heart was empty and contracted: all the valves were quite healthy. The large and flabby stomach contained about a pint of liquid food; it, as well as parts of the transverse colon, was firmly adherent to the lower border of the liver. The pylorus was patulous, readily admitting the thumb. The duodenum was empty: the papilla marking the opening of the common bile-duct into the gut, was prominent, as large as the end of the finger, and its orifice readily admitted a lead pencil. Just within the opening of the duct lay a gall-stone. The duct increased in calibre as it approached the liver, until it and the hepatic duct were dilated into a sac of about two ounces' capacity. The walls of this pouch were very thick and indurated, and there was a deposit of dense tissue round them. At the lower side of this sac, near the orifice of the gall-bladder, was a cup-shaped depression the size of half a chestnut; its floor and sides presented the shreddy surface indicative of recent ulceration. On the upper wall of this dilated duct, and immediately opposite where the blood vessels entered the left lobe of the liver, was a similar spot of ulceration, somewhat larger and irregular in outline: a little blood was observed to flow from the bottom of this depression, and here was found an opening communicating directly with one of the vessels entering the left lobe of the liver—the tissues in the vicinity were much matted, but it seems to have been established that this ulcerated vessel was a branch of the hepatic vein. The walls of the gall-bladder were much thickened; its mucous surface had wholly lost its normal honeycombed appearance: the opening between it and the dilated duct readily admitted the finger. Both the gall-bladder and the duct when opened contained a little bloody fluid. The right lobe of the liver was smooth and glistening, rather enlarged and slightly fatty. The left lobe presented a remarkable appearance. It was firm and smooth—not glistening; and its colour, on the surface and in section, was of an uniform greenish-brown slate hue. All appearance of structure was gone: it could be easily broken with the fingers, and the fractured surfaces had much the appearance of a nearly dried mass of mud treated in the same way. The larger blood-vessels were distinguishable: they were filled with a dryish brown-red material, which crumbled easily in the hand into a coarsely granular mass. The intestinal canal was nearly empty, containing only a little semi-fluid yellow fæcal matter: nowhere in this tube was there anything which looked like blood. The source of the hæmorrhage was doubtless the ulcerated blood-vessel supplying the left lobe of the liver—the blood readily finding its way through the dilated duct into the duodenum, and thence, through the patent pylorus, into the stomach. It is remarkable that all the blood appears to have taken this course, none of it passing down the bowel. The gas accumulating in the intestinal canal after death would seem to have made its way, by means of the same open vessel, to the right side of the heart. The peculiar condition of the left lobe of the liver is believed to have been caused by the complete shutting off of its blood supply, producing a necrosis of the part. Hæmatemesis, with the blood coming from such a source, must be exceedingly rare, and the case is probably unique.

Spurious Systematic Sclerosis of the Spinal Cord.—Under this title M.M. Ballet and Minor publish an interesting case in the January number of the *Archives de Neurologie* with a tolerably exhaustive commentary upon the intimate nature of the pathological changes discovered therein. The patient in question was a married woman, æt. 42, in whose antecedents syphilis was probable, though not proved. Her nerve disorder betrayed itself first by lightning pains in the legs, then amblyopia leading to complete amaurosis, and headache, but no vomiting. Three years later, weakness of the right arm was complained of, the legs became affected shortly afterwards. On examination there was some rigidity of all the limbs, and exaggeration of the so-called tendon-reflexes. After death, throughout the greater portion of the cord, there was found an extensive sclerosis of the lateral and posterior columns of the cord, and the object of the authors in their present communication is to show that these changes in the cord were not the same as those of ordinary systematic myelitis. In the posterior region for instance, although there was an ascending myelitis in the columns of Goll, reaching to the cervical region, still the affection of the columns of Burdach, or posterior radicular fasciculi of Kölliker, was chiefly in the dorsal region, and not, as in ordinary locomotor ataxy, chiefly in the lumbar enlargement. In the lateral columns the evidence against any ordinary systematic myelitis was still more clear for the process started in the pia mater, and spread inwards, affecting both the direct cerebellar and the pyramidal tracts, and disregarding the physiological barrier which separates them. As further evidence in the same direction, the authors point to the absence of any affection of the columns of Türck and corresponding regions of the anterior cornua, as is usually the case when the pyramidal tract is diseased. The atrophy of the optic nerves was similar to that often seen in cases of ataxy. Cases of combined sclerosis of the lateral and posterior columns of the cord have been occasionally recorded, and the authors divide them into five types, mostly mixed, *i.e.*, a combination of diffuse and systematic sclerosis. The prominent microscopical character of the latter form of disease, is the enormous increase of connective tissue and disappearance of the nerve tubes. In the case under consideration the nerve tubes were present in considerable numbers, and were mostly considerably increased in size, in some, the axis-cylinder was absent, in others it was swollen and varicose. The connective tissue corpuscles were increased in number and size. The walls and sheaths of the vessels were found to be infiltrated with nuclei and leucocytes, and the authors regard this as the initial lesion. They consider that there are two distinct modes of origin for sclerosis, and it may accordingly be perivascular or peritubular, though the former in time leads to the latter. The paper concludes with some considerations upon the symptoms resulting from a combined sclerosis of two or more different systems in the cord, they will of course depend upon the level of the cord at which the disease occurs.

Acute Myelitis due to Syphilis.—Chronic diffuse myelitis has long been generally recognised as often due to syphilis, and latterly we have been taught to accept certain forms of acute cerebral disease associated with arteritis as owning a similar cause, and we are now called upon to admit the importance of syphilis in the ætiology of acute myelitis. In support of this proposition, M. Déjerine has recently published an account of two cases (*vide Revue de Médecine*, January, 1884). In the first, the patient was a man, æt. 57, in whom symptoms of acute myelitis affecting the lumbo-

dorsal region appeared thirteen months after primary syphilis had been contracted. There was absolute loss of power and sensation in the legs, with incontinence of urine and fæces, the paralysis was quite flaccid and the skin reflexes were abolished. Ulcers formed on the abdomen from blisters produced by a poultice, and bedsores appeared on the sacrum and heels, the patient died from pulmonary troubles, four weeks after the commencement of the paralysis. In the second case, the patient was a man, æt. 38, in whom the symptoms of central myelitis came on a year after primary syphilis, there was absolute loss of motion in the legs, and the skin and patellar reflexes were abolished, there was complete loss of sensation in the legs, and paralysis of the bladder and rectum, the disease ran a more rapid course than in the other patient, and death occurred on the eighth day. The changes found in the nerve centres in these two cases were very similar, and may be said to have consisted of an acute central myelitis, in the lumbo-dorsal region, in the second case the changes being more limited to the grey matter than in the first case; the affection was both parenchymatous and interstitial, attacking the vessels, nerve-cells and fibres and neuroglia, in the first case there was much more evidence than in the second of an ascending and descending secondary myelitis. In both cases there was marked parenchymatous neuritis of the anterior roots, but the posterior roots were healthy. The lesions found in these two cases had no distinctive characters, and differed in no respect from those found in ordinary acute myelitis. This is fully admitted by M. Déjerine, and he points out that the unaided eye can generally determine the ætiology of a case with greater accuracy than is gained by means of the microscope. When dealing with any spinal affection clinically, the all-important thing to know is how the disease will terminate, whether the patient will die, recover completely, or remain paralysed, and the answer to this question can only be given by statistics. Against the syphilitic origin of acute myelitis, it has been urged that it is a rare sequela of syphilis; this, says M. Déjerine, is very true; but then it is also true that acute myelitis itself is decidedly rare, and judging from the cases hitherto recorded, syphilis is the only infectious disorder met with at all frequently in acute central myelitis, and when this latter occurs at a date not remote from the period of infection, it is impossible to avoid seeing in such an occurrence a spinal localisation of syphilis, and the conclusion is forced upon one that acute central myelitis due to syphilis is a reality.

Is Hydrophobia a Specific Disease?—The *New York Medical Journal* for December 29, 1883, publishes a paper, read by Dr. C. W. Dulles, before the Philadelphia College of Physicians, entitled "*Criticisms on the Specific Theory of Hydrophobia.*" The paper is one which scarcely admits of condensation, but the main points brought forward by the author are—the various and contradictory theories which are and have been advanced as to the nature of the malady; the conflict of opinion amongst past and present authorities as to its mode of communication; the equally contradictory and uncertain methods of treatment—which vary from throwing into a fish-pond (Celsus) to the inhalation of oxygen (Schmidt and Zebeden), with an almost universally unsatisfactory result; the various, varied, and mutually-contradictory views which are held as to its incubation period, its pathology, and the lesions which have been demonstrated in the course of *post-mortem* examinations—the same morbid appearances which were present in cases of hydrophobia having been noted in cases of purpura, diabetes, fracture of the skull, erysipelas, head injury with hæmatoma, concussion of the brain with fracture of the spine, delirium tremens, peritonitis, tubercular meningitis, mental deficiency and excitement, tetanus, uræmia, enteric and intermittent fevers, phosphorus poisoning, and—some of them—even in the brains of healthy dogs (Czorkov); and, especially, the unsatisfactory manner in which the whole subject has been treated—the way in which—the existence of rabies being suggested—facts are wrested, statements received as facts, and gaps in the evidence filled up by supposition, in order to support the diagnosis already assumed—*e.g.*, the madness of the suspected dog (or, where a bite is not remembered, the madness of a hypothetical dog which is supposed to have inflicted a forgotten injury), being often, if not usually, deduced from the diagnosis of hydrophobia in the man. As the result of his examination of the cases he has watched, and of the evidence upon which the commonly received theory of hydrophobia is supposed to rest, the author comes to the twofold conclusion that (1) "Hydrophobia is not a specific, inoculable disease, derived from the bite of a similarly affected animal. (2) If we wish to have an accurate, scientific knowledge of what too often actually takes place and is usually called hydrophobia, we must begin its study unprejudiced by the view hitherto generally entertained in regard to it, and with canons of criticism very different from those heretofore deemed sufficient."

Rupture of the Vermiform Process.—M. Polaillon, surgeon of the La Pitié, communicated to the Society of Medicine of Paris (*Union Méd.*, January 3), an interesting case of rupture of the ileo-cœcal appendix during an effort. A washerwoman, 19 years of age, and in the enjoyment of perfect health, while trying to lift a large bundle of linen, was seized with a sudden pain in the abdomen, accompanied by the sensation of something bursting. The pain kept increasing, together with great tenderness in the abdomen, especially on the right iliac fossa. Symptoms of intestinal obstruction appeared, and as no relief was obtained by the measures adopted, the patient was brought to La Pitié on the seventh day after the commencement of the symptoms. By this time her situation had become very desperate, and an incision was made in the left inguinal region, in order to search for the seat of obstruction. A discharge of fetid sero-purulent fluid announced that the intestine was already perforated, and that purulent peritonitis existed. Further exploration was not pursued, and an artificial anus was formed. The patient died ten hours after the operation, and abundant adhesions and suppuration were found at the autopsy. The vermiform appendix, in an inflamed condition, was found adherent at the upper aperture of the pelvis, and near its free extremity was an oval ulceration, in the centre of which was a rounded perforation; and a little distance above the ulceration a raw bean was found obstructing the calibre of the appendix, but moveable towards the cœcum. M. Polaillon observes that the case is remarkable as an instance of the rupture of the appendix by a mere effort, without any precursory signs, the subject being quite well at the time. Still, even in the absence of symptoms, it is evident that the foreign body had effected such a change on the coats of the appendix as to diminish their power of resistance and prepare the way for a rupture. The case also shows that peritonitis may give rise to the three symptoms, gaseous distension of the abdomen, fœcal vomiting, and the absence of the emission of gas *per anum*, the union of which generally indicates intestinal obstruction. The error in diagnosis, however, is more apparent than real, for the adhesions arising from peritonitis may readily cause obstruction of the intestinal canal.

REPORTS OF SOCIETIES.

CLINICAL SOCIETY OF LONDON.

Friday, February 8th, 1884.

Sir Andrew Clark, Bart., M.D., President, in the Chair.

Mr. Pearce Gould related the history of a case of

Spreading and Obliterative Arteritis,

the patient being shown. It occurred in a lad, aged nineteen, in whose family and personal history there was nothing to throw light upon the cause of the disease. The illness began in May, 1883, when the man noticed the fingers of his right hand becoming dark in colour; when warm the hand was of a deep red colour; when cold it became first blue, and then dead white, and there was then a sickening pain

in it. After three weeks he rested from his work (in a brick-yard) for three weeks; but, again, after working for a month, the hand became worse, and he had to rest for a month. He then thought himself well, but, on resuming work, "the pain went" into his forearm and elbow, and since then he had been unable to work. He was admitted into the London Temperance Hospital, on October 31st. The right forearm and hand were colder than the left—somewhat wasted; while the hand was warm he could wash with it, and it quickly became cold and painful; the pain was always worse at night. The brachial artery in its whole course was harder than the left, and less affected by the pulse, which ceased in it just above the elbow joint. The radial artery was felt as a prominent, hard, pulseless cord; there was no pulse in the ulnar artery. The other arteries of the body appeared normal. There was a small patch of dry gangrene on the tips of each of the first, third, and fourth digits. Heart, normal; accentuation of second sound over aortic cartilage. Urine, normal; temperature, normal. For about a fortnight there was no notable change, but then the pain increased, first at night, and then by day, until it became so severe that the patient writhed in agony, which was only partially subdued by repeated hypodermic injections of morphia and draughts of chloral and bromide of potassium. Concurrently with this, the pulse in the brachial artery faded away, until the vessel formed a hard, pulseless cord as high as one inch below the teres major tendon. On November 23rd the right subclavian artery was noticed to be very prominent above the clavicle, and the heart's action was excited. In December the pain lessened, and by December 17th was but slight, while the prominence of the subclavian artery was diminished. Now he is quite free from pain, and expresses himself as quite well. Nearly the whole of the last joints of the thumb and of the right ring finger have mummified, and are nearly detached. The limb is considerably wasted: the radial artery has so shrunk as to be scarcely perceptible, but is quite pulseless; the brachial artery is still felt as a firm pulseless cord to within an inch of its origin. Mr. Gould stated that at no time had there been any œdema of the part, or any loss of sensation, the only paræsthesia being intense pain, particularly complained of in the parts which afterwards became gangrenous. The temperature was normal on the patient's admission to hospital, but on November 26th, was found to be pyrexial, and it continued so, ranging between 99° and 101°, until December 18th, when it finally returned to the normal; on one occasion the temperature rose to 101·8°. Mr. Gould remarked that the history and progress of the case plainly indicated that the disease was a progressive obliteration of the arteries of the right upper limb, probably starting in the hand and spreading almost up to the axilla. There was no source of embolism discoverable, and the slow progression, the marked induration of the vessels before pulsation was lost, was sufficient to exclude simple thrombosis, especially in the arteries of the upper limb of a lad of this age. He believed that the disease was a primary inflammation of the arterial coats—arteritis obliterans—such as that described by Friedlander, and had been examined very carefully in one case by Winiwarter. Jaesch and others had reported similar cases, and the disease strongly resembled that described by Heubner in the cerebral arteries in syphilis. The present case, however, was especially noteworthy as occurring at an earlier age than any before recorded, and affecting the upper rather than the lower limb. There was no history or evidence of syphilis in his patient, and Mr. Gould was unable to fasten on the cause of the affection. It was important to notice the very small amount of gangrene that resulted from so extensive an obliteration of the main arteries of the part.

Dr. W. B. Hadden detailed a case of

Obliterative Arteritis.

An unmarried woman, aged 35, was admitted, under Dr. Bristowe, at St. Thomas's Hospital, on February 22nd, 1882. There was nothing of importance in the family history and no reason to suspect syphilis. The patient had been accustomed to sleep with an invalid child, and her arm, which was placed around the child, used to hang outside the bedclothes. Six months before admission she had severe pain in the right arm, shooting down the hand; and two months before admission the tips of the first and second fingers were hard and cracked. On admission, she was a healthy, well-nourished woman, without any visceral disease. She complained of constant pain, but occasionally shooting, in the thumb and first and second fingers of the right hand. The fingers were pale and cold, and on the tip of each there was a flat irregular corn. The thumb was pale, cold, and stiff, and top was hard and thick. There was no pulsation in the radial and ulnar, and the former was hard and tender. Pulsation was felt in the arteries at the bend of the elbow. Subsequently, pulsation could not be felt in the lower part of the axillary, and there was tenderness along the whole brachial. The hand and arm became very cold, and the fingers livid. Surface temperatures were taken, and it was found that the right upper extremity was much colder than the left. Later, the tenderness in the course of the arteries became more excessive, and the absence of pulsation extended higher into the axillary artery. The skin over the ends of the thumb and first three fingers became gangrenous, and was separated. Finally, pulsation returned in the brachial as far as the end of the elbow. Six months later the patient wrote to say that she was quite well, but that there was no pulse at the wrist. Prolonged pressure on the arteries seemed to be the exciting cause, just as it is sometimes in the case of a nerve. The favourable termination, as in paralysis, is worthy of note.

Dr. Mahomed observed that the further progress of such a case as Mr. Gould's should be closely watched, and mentioned a case which he had himself published in the *Medical Times and Gazette* ten years ago, in which a progressive arteritis in the subclavian artery had been accompanied by attacks of angina. The *post-mortem* examination had shown that the disease had progressed along the great arterial trunks, and finally invaded the coronary arteries of the heart. He thought it not impossible that a similar train of events might follow in Mr. Gould's case.

Mr. Bryant would like to ask a question of the authors of the two papers, with respect to the origin of arteritis, a condition fully recognised in itself, but of which the causes were less well known. Might there not have been thrombosis in Mr. Gould's case, setting up subsequent arteritis? With respect to the bony prominence in the neck, he would suggest the possibility of its being an extra rib, and, further, that the artery, from having been pressed against it, might have sustained some injury. In Dr. Hadden's case also, there was localised pressure, which would be much more liable to produce thrombosis than arteritis. He instanced the familiar treatment of aneurism by local pressure as an example of this.

Mr. Harrison Cripps remarked that the diagnosis in Mr. Gould's case appeared to have been arrived at rather by a process of exclusion of other causes of obliteration, than by any very definite evidence of arteritis. He did not think that the present condition of the vessels could be truly attributed to arteritis proper. Having examined the case carefully, he was inclined to think that the prominent mass in the neck had pushed forward the subclavian

artery, gradually diminishing the circulation, and giving rise to clotting, as in the pressure treatment of aneurism. Though arteritis was a rare occurrence at so early an age, there were cases on record of exostosis in even younger persons. He related the particulars of the case of a young man, aged 21, in whom an exostosis had given rise to pressure upon the subclavian artery.

Mr. JONATHAN HUTCHINSON, after some remarks complimentary to the authors of the papers, mentioned a series of three cases of arteritis, in all of which, however, there had probably been antecedent atheroma. In one case, complicated with syphilis, there had been gangrene of the ends of some of the fingers, attributed to arteritis, and accompanied by severe pain. In the second case, pain and redness of tortuous temporal arteries, due probably to the pressure of the hat, had been followed by recovery, with obliteration of the vessels. There was no syphilitic taint in the case, but there were probably some senile changes in the vessels. The third case, which more nearly resembled Mr. Gould's, was that of progressive ascending arteritis, following a slight burn, and rendering amputation at the shoulder joint necessary. The arteries when subsequently examined, were found to be filled with clot, completely plugging them from end to end. In the opposite arm the vessels were tortuous, but not calcareous. He considered that in the present case, either arteritis or periarteritis had caused swelling of the coats of the vessels and thrombosis. He agreed with Mr. Cripps in questioning the purely arteritic causation of the obliteration. We ought to keep our minds clear upon the subject of arteritis, especially as to the absolute cause of it. Assuming that the local pressure was the cause of the mischief, it was interesting to note that the subsequent changes had begun peripherally, and not locally.

Dr. ANGEL MONEY had recently had the opportunity of examining the spinal cord in a case of lead paralysis, and had been struck with the marked changes present in the vessels. He suggested the possibility of lead-poisoning as a factor in the production of arteritis.

Mr. J. H. MORGAN explained that the case described by him, and quoted by Mr. Gould, was probably one of periarteritis. The man, aged 60, had suffered from syphilis. The vessels had become affected one at a time, the inflammation passing gradually down, with local pain. The vessels of the arm, neck, and leg, were attacked in turn, but no obliteration of their lumen had taken place at any time, and they differed thus from the vessels in Mr. Gould's case. In the latter, he thought that the arteritis was open to question, especially as he understood that the gangrene had preceded the pain; which might have been due to pressure upon a nerve trunk, as well as upon the artery.

Mr. PEARCE GOULD, in reply, observed that the discussion had turned chiefly upon the nature of the case. With respect to the pain, it had undoubtedly preceded the gangrene. While adhering to his belief that the process had been essentially arteritic, he did not mean to assert that there had been no thrombosis. The bony mass in the neck, he believed to be symmetrical, since there was another swelling upon the opposite side of almost the same size. He was at a loss to understand how pressure upon a main arterial trunk could cause peripheral clotting. The subclavian artery, in his case, had at first appeared to be normal, but there had subsequently been marked bulging of the vessel forwards, and afterwards a gradual recession to its former position. His case differed essentially from those of the elderly patients which had been mentioned. He remarked on the expansion of the vessel and the hypertrophy of the heart, which had been overlooked in the discussion.

Dr. HADDEN replied briefly.

Dr. BURNEY YEO read a case of

Pyrexial Syphilis.

This case was admitted into King's College Hospital on October 10th, 1883, with symptoms of pyrexia—high temperature, with great diurnal fluctuations, twice reaching 105° F., and four times 104° F., and averaging in the evening for three weeks from 103° to 104°. The daily oscillations were often more than 6° F. The other symptoms were pains in the limbs and trunk, headache, thirst, sleeplessness, great debility, and rapid emaciation. Between a fortnight and three weeks after his admission symptoms appeared, chiefly on the back and legs, resembling imperfectly developed variolous pustules without the areola. Considerable doubt as to the nature of the case was at first felt, but after he had been in the hospital three weeks he confessed to one of Dr. Yeo's clerks that he had venereal sores on the penis. Anti-syphilitic treatment was attended by a rapid fall of temperature to normal, rapid improvement of nutrition, and recovery of strength, and rapid drying up of the pustular eruptions. He left the hospital on December 20th, having been for some time quite free from symptoms of any kind. The chief peculiarities of this case were—1. The great and continued elevation of temperature, and its great daily oscillations. 2. The early appearance of the pyrexia, within 25 to 30 days of the exposure to infection. 3. The absence of any definite relation between the temperature and the eruption, which was not fully developed till three or four weeks after the onset of fever. 4. The occurrence of profound constitutional affection without any noticeable induration about the local sores. Dr. Yeo, in conclusion, called attention to the opinions expressed by Sir William Gull, Sir James Paget, Mr. Hutchinson, and others, in the debate on syphilis at the Pathological Society, and referred to Güntz's observations on the pyrexia of syphilis. He also pointed out the important pathological analogies and practical suggestions to which a case like this gave rise.

Dr. MACLAGAN observed that the idea that syphilis is really a pyrexia, is gradually gaining ground, but there are very few cases on record which illustrate the theory so clearly as the present. He commented upon some of the doubtful points in the case, especially upon the vesicular nature of the rash, which is in itself very rare, and is even denied by some authors. Regarding the fever alone, it certainly resembled some of the anomalous forms of typhoid, and he suggested the possibility that the fever itself might have some such origin, or be due to a blood-poisoning; the syphilis being accidental.

The PRESIDENT was quite sure that vesicular rashes do occur in syphilis. He had himself seen cases with rise of temperature and abundant vesicular eruption.

Mr. JONATHAN HUTCHINSON thought there could be no doubt about the syphilitic pyrexia, having experience himself of many similar cases. Possibly, the fever had sometimes passed unobserved, owing to the less elaborate clinical observations in surgical than in medical wards. With regard to the eruption, he thought that it would be no more incorrect to speak of varioloid syphilis, than of syphilitic psoriasis. The form of the rash was sometimes so exactly similar that cases were not infrequently sent into small-pox hospitals. He mentioned a case in private practice in which the most elaborate precautions had been taken to isolate a case of supposed variola, which, however, had only improved under the usual specific treatment. Possibly, the highest temperatures were co-existent with the most abundant rashes. In the present case, the absolute date of contagion could not be fixed with certainty.

Dr. BURNEY YEO mentioned that the blood and the secretions from the sores had been examined by Mr. Watson Cheyne, but no specific organisms had been found.

Dr. DUCKWORTH had seen several cases of syphilitic fever, and chiefly in women. Rapid recovery had generally taken place under the usual treatment.

Mr. MORRANT BAKER suggested the possibility that the diagnosis of syphilis might be open to question, since the sores on the penis were not hard, the glands in the neighbourhood had not been enlarged, and the nature of the rash had not at once suggested itself to Dr. Yeo.

Dr. COUPLAND enquired whether there had been anything in the condition of the sores on the penis, which might have given rise to septic infection.

Dr. TONGE-SMITH referred to a case admitted into the London Fever Hospital, with rash and temperature fluctuating between 103° and 98°, in which enlarged glands and loss of hair had suggested anti-syphilitic treatment, under which a rapid recovery took place.

Mr. STRUGNELL mentioned a similar occurrence at a small-pox hospital.

Dr. BURNEY YEO, in reply, observed that the temperature chart certainly resembled that of typhoid fever, in some respects; his case, however, had been closely watched for three weeks, and had been positively diagnosed as syphilitic by one of his colleagues. The question of septic infection had arisen, but there had been no reason to suspect its existence.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

TUESDAY, FEBRUARY 12TH, 1884.

JOHN MARSHALL, F.R.S., President, in the Chair.

On Alcoholic Poisoning.

DR. W. H. BROADBENT read a paper on this subject, of which the following is an abstract:—

A case occurring in a gentleman, aged 42, was related. He had developed a liking for wine in early manhood, and had gradually become inert and sedentary, spending most of his time in bed, reading and drinking port. In 1875, he was placed under the care of Dr. Harrison, of Shepherd's Bush Green, as a dipsomaniac. He never had pronounced delirium tremens, but had been wakeful and nervous, and for some months before his final illness had been failing in mental power. The paralysis came on very insidiously; the arms had been noticed to be weak for a fortnight, but there had been no great interference with the use of his hands in holding his paper or conveying drink to the mouth till within a few days of the first consultation between Dr. Harrison and himself on April 3rd, 1883. At this time the paralysis was chiefly manifest in the extensor muscles of the forearms, giving rise to double drop-wrist, but the flexors were also weak, and the muscles of the trunk were enfeebled, and although all movements of the legs were freely effected in bed, he could not stand alone. The knee-jerk was lost, the sole reflex marked. Sensation was unimpaired, the sphincters were not affected. A special peculiarity was the pale, puffy, purplish condition of the hands, while the feet, when hanging down, could be seen to swell. The urine contained neither albumen nor sugar. The pulse was frequent, and small, and weak, but regular. The first sound of the heart short and followed immediately by the second at too brief an interval; there was no valvular murmur. A week later the paralysis had so far increased that the hands lying alongside the body could not be placed upon it, and the legs could not be drawn up in bed. There was also obvious paralysis of the diaphragm, which soon gave rise to respiratory distress and to difficulty of speaking. Next day the lower ribs, which had previously expanded well, only moved upwards with inspiration, and death took place from asphyxia on the 11th. On *post-mortem* examination of the cord (which was all that was permitted) it was found to be remarkably pale, but its consistence was normal, and no change could be found on microscopical examination, which was carefully made by Mr. Silcock. Other cases, essentially similar, had been seen by himself with the late Dr. Rhodes, of Weymouth, in a lady aged about fifty; with Dr. Myrth, of Harrowgate, in a lady aged about thirty; with Mr. G. Amos Duke, in the wife of an inn-keeper; in a deserted mistress in St. Mary's Hospital; and in a gentleman, aged thirty-nine, with Mr. Wheeler, of Chiswick. In another case, seen with Dr. Morton, the later symptoms did not altogether correspond with those described. In all alcohol had been taken in unusual excess, and he considered himself justified in considering it as the cause. Most of the patients were females of sedentary mode of life, and the case described was in a gentleman who scarcely ever went out and spent most of his time in bed. It was thought probable that the absence of exercise was the determining cause of the alcohol affecting the cord. The disease most resembled acute ascending spinal paralysis, differing chiefly in the order in which the different parts of the cord were attacked, the double wrist-drop at an early period being highly characteristic.

DR. WILKS said the subject was one which had long interested him. The effects of alcohol on the nervous system were ill understood at present; he was glad that so able an authority as Dr. Broadbent had taken it up. It was curious how some people were more liable to suffer than others, and how also some organs were more susceptible than others. For instance, a person went on for a while taking alcohol without noticeable effect, then he got dropsy and his liver became affected; while in another case it was the brain which seemed to suffer. It was curious also to note that women were more frequently affected than men. In the brains of those dying with delirium tremens, no structural changes were appreciable, although the membranes were found thickened. This disease is more common than the author of the paper seemed to think. He (Dr. Wilks) was constantly meeting with cases; it was remarkable, however, how they recovered from the disease, if patients would only leave off their alcohol; recovery, indeed, occurs even in the severe cases, with perseverance in treatment; this was proof positive that there could be no structural changes. Alcohol was supposed to give rise to fibroid changes in the nerve centres; but he had seen cases recover completely, notwithstanding, provided the cause were removed; a year's rest in bed, with electricity, might be required; hence he thought there was no hard-and-fast pathology. Were Dr. Broadbent's cases typical? If alcohol had any specific effect, the symptoms, he imagined, would necessarily vary with the part chiefly affected. In the myelitis of syphilis the symptoms varied in this way, and why should they not do so in alcoholic disease, if alcohol really gave rise to any specific morbid change?

DR. BUZZARD said the fact that the disease was not a new one in no way detracted from its interest. With characteristic modesty, Dr. Wilks had not referred to his own writings on the subject, published some twelve years ago. He agreed with Dr. Wilks that, although there were general resemblances in the cases, there were nevertheless differences. Contractions did occur, and sometimes persist, yet the muscular paralyses might occur without them. In his own experience lancinating pains were not uncommon. In some cases also hyperalgesia was so marked that the patients could hardly bear the weight of the bed-clothes. He had found that the muscles reacted less well than normal to the constant current, but with exaggeration to the interrupted current; this showed the lesion to be in the spinal cord, and resembled what existed in lead-poisoning. Although no pathological lesions could be discovered in the spinal cord, yet atrophic changes had been found in the nerve trunks, such as were sometimes found on the trunks after injury to the multipolar cells in the anterior horns. Two or three years ago Dr. de Watteville had suggested that a dynamic change in the cord was the probable cause, a temporary arrest of function; the cord being a trophic centre, atrophic changes in the nerve trunks proceeding from it were brought about. Personally, he had never seen a fatal case, but had been surprised to see how patients recovered, either after two or three attacks. His cases were mostly females. He had seen some cases in women of active employment, and he could not, therefore, attribute the condition to the want of

proper exercise. The electrical test was the best means of differentiating between this disease, and acute ascending neuritis.

Dr. Wilks rose to add that he quite concurred as to the lancinating pains, Dr. Anstie, many years ago, had drawn attention to them.

Dr. Barlow could recall four cases of alcohol paraplegia, all occurring in women, aged respectively, 26—31, 30, 40, and 60 years. In all there was some hyperalgesia; and though neuralgia was absent, the patients all resented handling. The contractions were not quite like those of amy-otrophic disease; they more resembled the uncontrolled action of antagonistic muscles. There were no pupil changes, both the upper and lower limbs were affected, and there was muttering delirium in two of the cases. Three recovered, and one died. In the fatal case, had alcohol and chloral been entirely discontinued, he felt sure that recovery might have taken place.

The President apologised for Dr. Broadbent's unexpected absence, and regretted that there could be no reply to the criticisms which had been made. The fatal nature of all Dr. Broadbent's cases was in marked contrast to what some of the speakers had said on this part of the subject.

Description of the Microscopic Preparations sent to the President.

By Dr. Straus, of Paris, Chief of the French Scientific Mission for the Investigation of the Cholera in Egypt, who gave the following description of them. They consisted:—1st. Of two preparations of the *rice-water stools* of cholera patients, stained with gentian violet. There will be found in these an innumerable host of organisms (various bacilli, micrococci and bacterium termo) of every kind, none of which, however, present anything very characteristic. 2ndly. Of eight *sections of the small intestine* (principally of the ileum) made from specimens hardened in absolute alcohol. These sections have been stained with methylene blue, and are mounted in Canada balsam. Those which are marked No. 1, came from a patient who died on the fifth day of the attack; No. 3, was taken from a patient who died at the end of the second day; No. 18, from one who died thirty-six hours after the commencement of the disease; No. 23, from one who succumbed at the end of the third day; Nos. 12 and xii, from a patient who, having had marked typhoid reaction, died thirteen days after the first attack. Most of the autopsies were made *immediately* after death. The latest amongst those from which the specimens were taken, was that from which No. 18 was obtained, which was made seven hours after death, an already late period in a country so hot as Egypt. Upon these sections there will be found:—1st. A complete desquamation of the epithelial covering of the villi and of the intestinal mucous membrane. 2ndly. In the substance of the mucous membrane, in the tissue of the villi, in the lumina of "Lieberkühn's follicles," and here and there, in the sub-mucous tissue itself, various Schizo-mycetes stained with methylene blue. The greater number of these are bacilli, and amongst them *there is one, which is the most frequently met with, short, thin,* and *straight,* and which is probably that which Dr. Koch has likewise seen, which he compares with the bacillus of glanders, and which he believes to be the cholera organism. "However, I dare not affirm," writes Dr. Straus, "that this is the organism seen by Dr. Koch, for that observer has not given the technical method employed by him in order to stain his microbe; but, for my part, it is more than probable that this latter is the same as that which is found in such great numbers in my preparations." Besides this bacillus, however, there is to be met with in these preparations another *larger one,* also some short thick bacteria, and, furthermore, numerous micrococci, situated in the substance of the intestinal mucous membrane.

Mr. Horsley described Dr. Straus's microscopic specimens; he said that he had found all the organisms described by Straus; but was quite unable to say that these organisms were at all characteristic of, or peculiar to, cholera.

Mr. Macnamara read extracts from a letter which he had received from Dr. Koch, now at work in India, in which he (Koch) expressed his full belief in the organism view of the nature of cholera, although he had hitherto failed to produce cholera artificially by injections or inoculations. He had made some further investigations, but was not at liberty to publish the results at present, but it was hinted that the special bacillus had been separately cultivated, and that the cholera could be artificially induced by their use.

Dr. Thin thought that, before we could speak with certainty as to the effects of the cholera poison on the intestinal tract, it would be desirable to institute a series of observations in man and animals, on the minute anatomy of the intestinal mucous membrane.

Sir Joseph Fayrer said he was one of those who did not believe in the communicability of cholera from person to person. Until it was shown that cholera could be produced artificially by injecting these bacilli, he could not accept this germ theory as the cause of cholera, nevertheless great good must result from the minute study which was now being devoted to the subject. He failed to see the grounds on which it was maintained, that cholera had been imported into Egypt; on the contrary, there was abundant reason to explain its outbreak in the insanitary conditions which everywhere prevailed.

Dr. Buchanan pleaded that Koch's views had not been fairly reproduced by Dr. Straus; for Koch had not said that any one of the organisms described was *the* organism of cholera. In Egypt, the epidemic was dying out, and on this account Koch had gone to India to continue his researches. So far, the germs described as present, appeared to Koch to be the effect, and not the cause, of cholera. Koch was, however, continuing his experiments.

Professor Lewis (whose long experience in India allowed him to speak with some authority) said that for years past he had been familar with the various organisms described by Straus; he should, however, hesitate before admitting that any of them were peculiar to cholera. He agreed with Sir Joseph Fayrer, that cholera is not communicable from person to person—that is to say, he had never personally observed such cases.

The President thanked those who had taken part in the discussion. He proposed that the specimens should be submitted to a small committee of experts for further examination and report, as the subject was one of great importance.

The meeting then adjourned.

EPIDEMIOLOGICAL SOCIETY.

Wednesday, February 13th, 1884.

Norman Chevers, Esq., M.D., C.I.E., President, in the Chair.

After some preliminary business had been transacted, the adjourned debate on Surgeon-General Hunter's paper was resumed.

Sir William Smart commenced by observing that one method of the introduction of cholera into a district was by the importation of fresh specific germs. Dr. Hunter had adduced, in his opinion, ample evidence in support of the view that the disease was endemic in Egypt, and not

imported. There was no doubt that the disease had become epidemic at Damietta, and travelled up the Nile. It was to be noted that several of the epidemics had in reality only been recrudescences of their predecessors. From 1866 until last year the germs had not been strong enough to produce more than cholerine cholera nostras, or choleraic diarrhœa, when cholera again appeared. After passing in review the history of cholera, he alluded to Watson's statement in 1843, that cases had occasionally occurred in this country since the outbreak in 1832. Epidemics were apt to be spread over a long period of time, thus, one began in Europe in 1847 and lasted till 1861. In conclusion he stated that he most perfectly coincided in every particular with Surgeon-General Hunter.

Inspector-General LAWSON said that the real point at issue was as to whether cholera could be conveyed by human intercourse alone, or in other ways alone, or not. The question had been before the profession for 50 years, but they had done very little to solve it. They had acted on partial information and theoretical conclusions, whereas true advance could only be made upon facts and a rigid analysis of them. Ten years ago he had read a paper before the Society urging these points. Very often when cholera broke out at a place, there was evidence pointing to importation, and there was also evidence that the disease had been pre-existent. Such cases were useless for the purpose in hand. Cases must be sought for where both kinds of influence were not at work, *i.e.*, where importation of the disease could be excluded, as in the epidemic of 1865 in this country. Dr. Hunter's report excluded one factor in regard to the outbreak in Egypt, and left therefore only one factor to be taken into consideration. In a matter of this sort, facts and the strict logical deductions from them alone should be dealt with. If the arrival of a case of diarrhœa into a healthy neighbourhood from a cholera district were followed by an outbreak of cholera, everyone would say that the case of diarrhœa had been one of cholera. He thought the expression, origin de novo, an unfortunate one; nothing occurred without adequate cause, and cases did not occur by chance. In the Registrar-General's report, deaths from cholera formed a fluctuating quantity, and during an epidemic there was an increase in the mortality from the malignant cases. On every occasion when there had been a marked increase of cholera here, there had been an epidemic somewhere in the neighbourhood. In 1869, during an epidemic in the South of Europe, there had been a marked increase of cholera in this country, with distinct outbreaks at Southampton Water, at a village in Yorkshire, at a prison in Manchester, and at Wick. Sometimes such a manifestation preceded the arrival of an epidemic. Cases of sporadic cholera were part and parcel of the epidemic, owned the same causes, and were an indication of the existence of those same causes. From other facts to which he alluded, he was led to conclude that the active cause of cholera might reach a place without communication at all from elsewhere, either for an isolated case or for an epidemic.

Dr. THRUPP said, he thought that the evidence collected by Dr. Hunter, in the short space of two months, was convincing proof that, between 1865 and 1883, cholerine, choleriforme, and cholera nostras, had existed throughout Upper Egypt. He considered the all-important question to be, what was the clinical and pathological connection between these three disorders and cholera? Dr. Hunter said, that in India they were the same, and he (Dr. Thrupp) hoped the point would be settled that evening. Both in India and in Egypt a like disease existed in a permanent form, and a like disease occasionally in epidemics. Why was it called cholera in the one case, and not in the other? He thought a cholera germ was as great a myth as the sea-serpent. He concluded by stating the following propositions:—1. The so-called types of cholera were not really different diseases. 2. The disease had in each country an endemic and epidemic phase, and the laws which converted the first into the second were dependent on local, climatic, and meteorological conditions.

The PRESIDENT asked whether cholerine, cholera nostras, &c., were always existent in India, as that had not been his own experience.

Dr. THRUPP replied, that he had been quoting Dr. Hunter, and he agreed with him, that all these diseases did exist there, and represented an endemic and modified form of the disease.

Dr. LONGHURST thought that, as a nation, we had neglected our duty in not studying this disease further. He had long ago suggested the appointment of a committee to investigate it in India, but nothing had been done. He considered that Dr. Hunter had proved that the disease was cholera, and that the epidemic was the outcome of a disease the history of which had proved that it belonged to Egypt just as much as to India. He thought that it was not an endemic disease in the sense that it was always amongst the persons, but rather that it was a climatic disease ever prevalent. He was strongly of opinion that it was a specific entity, though the germ could not be recognised by our present methods of investigation. Quarantine was utterly useless.

BRIGADE-SURGEON SCRIVEN, after correcting an important verbal error which had accidentally been made in our report of his speech at the last meeting, and for which we have to express our sincere regret, said that he did not hold very strongly to the de novo origin of cholera. He said that we were accustomed to regard the Delta of the Ganges as its home, and to believe that it did spread. The possibility of all sources of importation had not been as yet excluded—*e.g.*, by pilgrims from Mecca. As to the disease being endemic in Egypt, this was not fully proved; the cases were too vaguely given, the clinical records were imperfect, and there was very little evidence of its tendency to spread. We had to find out whether cholera was still prevalent in Egypt, if it had no home in Egypt, either it had already ceased, or would do so very shortly. The local practitioners should rely upon suppression of urine and fall of temperature, as the two most important symptoms. In India all cases of purging and vomiting were accounted by the natives as cases of cholera, and he quoted three instances to show how fallacious this opinion might be.

Dr. CULLIMORE made some observations to the effect that there was an *à priori* presumption that the disease was imported. The meteorological conditions present favoured its spread. He believed in the truth of Dr. Koch's discoveries.

Sir W. J. HUNTER, in reply, briefly alluded to the honour conferred upon him by the Queen which had just been mentioned by Sir J. Fayrer; he said his motto in regard to that was "Je suis avant tout, je suis un médecin." He was pleased to find Sir W. Smart and Dr. Lawson in such entire accord with himself. Dr. Thrupp's question gave the real key to the position, and he replied to it by another question, viz., when a case came with purging, vomiting, prostration, aphonia, anuria, cramps, and symptoms of an algide state, that was cholera; sometimes the symptoms were not so marked, but this group of symptoms always signified cholera. He referred to his report, where cases in America had been described under various names, but all in reality cases of cholera. Cases of cholerine, &c., might vary in degree, but they were one and and the same thing. He could see no difference between the cases in Egypt and the cholera he had seen in India. As to "typhus-cholera," he was in no way responsible for the opinions of others. He admitted that the details of the cases were insufficient; but the evidence was that of medical men, whose notes had been burnt in Alexandria, and who therefore had only their memories to rely upon, but this made him the more inclined to accept their statements. He hoped that further observations would be made. There was no subject upon which opinions were more numerous, or facts more scanty. He challenged anyone to prove the importation theory. The difficulties of his investigation had been much increased by the political and mercantile considerations which so embarrassed this question in Egypt.

Sir W. SMART proposed a vote of thanks to Sir W. J. Hunter.

Sir W. J. HUNTER read a letter from Dr. Buchanan, containing the following extract from Bacon:—"It is recorded by competent observers that if you take earth from the side of the Nile, and protect it from wet or waste, and weigh it every day, you will find that it remains always of the same weight until the 17th of June, when it begins to increase in weight, and continues to increase in weight during the whole time that the river is rising. This can be due to

nothing but the air, and this is the more extraordinary, *because it has been observed that just* AT THAT DATE *it is the habit of grievous plagues to make their appearance at Cairo.*"

Dr. CHEVERS, on behalf of the Society, briefly thanked Sir W. J. Hunter for his important contribution to State Medicine.

OBITUARY.

ALEXANDER THOM THOMSON, F.R.C.S., J.P.

MR. ALEXANDER THOM THOMSON, who died at Oldham, on the 29th ultimo, was born at Montrose in 1820. He received his education at Edinburgh, and became L.S.A. in 1843. In the same year he also took the membership of the English College of Surgeons, the Fellowship of which was conferred on him fifteen years later. Mr. Thomson practised at Cheadle, in Cheshire, from 1843 to 1854; in the latter year he removed to Oldham, where he soon acquired a very large connection. In 1864, he broke down, with symptoms of degeneration of the cerebral arteries. He obtained the help of a partner, and having in some measure regained his health, was enabled to take a fairly active share of work, until September, 1873, when a small cerebral hæmorrhage, attended with transient hemiplegia, again incapacitated him. From this time till his final retirement from practice in 1876, he was only able to undertake a comparatively small amount of active labour. After giving up practice, Mr. Thomson, having been appointed in 1879 J.P. for the county of Lancaster, devoted himself with energy to his magisterial duties, both on the bench, on the county finance committee, and as a visiting justice to the asylums. For some months before his death he had been conducting, with much interest, a physiological class for young men, and it was in returning from a meeting in connection with this work, in the teeth of the storm of January 26th, that the final fatal attack of cerebral hæmorrhage took place. He was seen to fall down in the roadway, was carried home, and died, without recovering consciousness, on January 29th. Mr. Thomson was a man of considerable talent, and though he never contributed to the literature of his profession, kept himself well abreast of contemporary science. He was skilful in diagnosis, and was frequently called in as a consultant by his fellow practitioners. He was an excellent man of business, and his council was constantly sought on other than purely professional matters. He took an active share in the organisation of the Oldham Infirmary, twelve years ago, and succeeded at the time in obtaining recognition of the principle of payment for medical services. He had great moral influence over his brother practitioners, and was on many occasions successful in smoothing professional differences. His social gifts were considerable, and he will be greatly missed, not only by his own immediate family, but by the social circle of which he had been for long the centre.

GENERAL CORRESPONDENCE.

A PROTEST.

[To the Editor of the Medical Times.]

SIR,—In the interests of humanity admit our protest against the practice of the profession at home who retain consumptive patients till the colliquative sweats or intractable diarrhœa indicates the thorough hopelessness of these cases, and then recommend an Australian voyage as a means to an unattainable result. We are not disposed to deny the rationality of such prescription for maladies of this class in their incipient phase. The balmy atmosphere south of the equator, the bromine, chlorine, iodine exhaled from the sea and coming in contact with the morbid lung at every inspiration are fraught with reparative influence of the most effective character, while the expanse of our continent furnishes every variety of climate suitable for the peculiarities of each individual instance. But can anything short of supernatural power restore patients, who with pulmonary cavities as large as emu eggs, are borne in scores on board the vessels to find an ocean grave or expire among strangers in the Antipodes, bereft of those consolations which family affection would have supplied. Very few ships we clear with the history of the voyage of which some incident of this character is not connected. Sometimes a death occurs at sea; sometimes an emaciated creature is sent to a public hospital to die, the hotels refusing to receive him; sometimes the funeral takes place from the ship's side. Whatever aspect the closing scene in each case may present, we imagine it must be affliction to the patient, the cause of remorse to his domestic circle, and a reflection on the moral and professional character of his former medical attendant.

D. P. MACLEAN, } Health Officers,
E. G. FIGG, M.D., } Port of Melbourne.

January 1st, 1884.

MEDICAL NEWS.

LABOURERS' DWELLINGS IN LIVERPOOL.—In accordance with the directions of the Liverpool City Council, their engineer, Mr. Clement Dunscombe, has reported on the class of dwellings most suitable for the accommodation of the lowest stratum of the working classes at the rate of a shilling per week per room. The report is sanctioned by the medical officer of health. Mr. Dunscombe thinks the nearest approach to the houses required by the Corporation are the Peabody buildings in London; those in Salford, lately erected under the auspices of the Manchester and Salford Working-men's Dwellings Company, Limited; and the blocks now in course of erection on Nash Grove, Liverpool. The rent, however, is above the specified amount in all of these cases, and it will be difficult, and sometimes impossible, to make such dwellings a financial success if the rental per room is limited to a shilling a week. Mr. Dunscombe has therefore proposed certain modifications, by which we hope the problem may be solved.

RESEARCHES UPON INFECTIOUS STOMATITIS AND NOMA.—A grant from the Research Fund of the British Medical Association was accorded to Mr. Alfred Lingard in August last for the above purpose, and he requests us to state that he will be very glad to hear of any case of noma which he could visit, either in London or in any part of the country. Communications should be addressed to Mr. Alfred Lingard, 49, Lambeth Palace-road, S.E.

NATIONAL HEALTH SOCIETY.—The Worshipful Company of Clothworkers has been pleased to grant a donation of 21*l.* to this most active and useful Society.

ROYAL COLLEGES OF PHYSICIANS AND SURGEONS, EDINBURGH.—*Double Qualification.* The following gentlemen passed their first professional examination during the January Sittings of the Examiners:—John Struthers Stewart, Lanarkshire; Chandos William Hoskyns Abrahall, London; George Arthur Herbert Woodforde, London; Charles Cochrane Dickson, Galashiels; Emmanuel Portal, Mauritius; Charles Jenkins Lumpkin, Sierra Leone; Ernest Goode, Birmingham; Hugh St. David Griffiths, Cheltenham; Evan Jones, South Wales; Frederic Julian Stone, Glasgow; Hamilton Edward Leonard Earle, Plymouth; Lionel George Wright, Colombo, Ceylon; John Arthur, Co. Derry; Henry Joshua Angustine, Calcutta; Robert Michael Forde, Lisanby Cottage, Cloyne; Hammond William Rufus Richardson Crosse, Middlesex; Parvah Nath Datta, Bengal; George Martin Giveen, Blackrock, Co. Antrim; James Bernard Wall, Blyth, Coleshill, Birmingham; Godfrey Ernest Garde, Timsleague; Edward Davies, Barmouth; Robert Morrison, Toberdoney; Samuel Wimbush, Heslerton: Thomas James Galloway Ganett, Exeter;

John Harford Jones, Merthyr Tydvil; Richard Power Rankin, Victoria, Australia; James Gray, Keith; Henry Peter, Stuybertsiz, Ceylon.

And the following gentlemen passed their final examination in February, and were admitted L.R.C.P., Edinburgh, and L.R.C.S., Edinburgh:—John Struthers Stewart, Lanarkshire; Charles Edward Morris, Campden; Charles Jenkins Lumpkin, Sierra Leone; Richard Nason Gaggin, Balby; Richard William Cæsar Hamilton, East Lothian; William James McFarland, County Tyrone; John William Irvine, San Francisco; Allen Adair Dighton, Gloucestershire; Joseph Bowerman Drew, Stow-on-the-Wold; John Hanson, Weeting, Norfolk; Augustus William Dalby, Jedburgh; Joseph George Garibaldi Corkhill, Liverpool; Archibald Harper, County Monaghan; Robert Knox Carleton Graham McCorkill, Canada; Lewis D'Almeida, India; Thomas Adam Beresford Kane, County Armagh; Maurice Stack Cussen, County Kerry; Charles Horace Barkley, London; Arthur Nathaniel Barnley, Bedfordshire; William Holberton Square, Kingsbridge; Ernest James Flynn, Dublin; Herbert Longmore Grant Chevers, Calcutta; Hamilton Edward Leonard Earle, Plymouth; Oliver Grenville Taaffe, Sherbourne; William Richard Coudon, Tipperary; William Frederick Hamilton, Londonderry; Richard Ferdinand O'Farrell, Galway; Ernest Howard Goode, Birmingham; Samuel Oliver Eades, India; Charles Reidy, Limerick; Edward Hodges Goggin Phillips, Limerick; John Henry McAuley, Randalstown; James Orr, Kilbride; John Joseph Hanly, County Tipperary; Simon Vincent Daly, Cork; Alexander James Griffith, County Leitrim; John McMichael, Dublin; Donald Alexander MacCrimmon, Ontario; Edward Flood McGragh, County Cork; Henry George Thomasz, Ceylon; Thomas Francis Hanly, County Tipperary; William Gibb, Dundee; Richard Fitzmaurice, County Cork; William Robinson, County Derry; David Matthewson Nairn, Dundee; Joseph Amy, Jersey; Alexander Willox McFadyen, Stirling.

Royal College of Surgeons of Edinburgh.—During the January Sittings of the Examiners, the following gentlemen passed their first professional examination:—Samuel Garland Sharpe, Norwich; and Louis Edgar Portal, Mauritius; and the following gentlemen passed their final examination, and were admitted Licentiates of the College:—George Lowbridge Baker, Dorchester; Edwin Harold Brown, Bombay; and Henry Edwin Dobie, China. Mr. George Dall Orrock, of Edinburgh, having passed his final Examination, was admitted L.D.S., Edinburgh.

A New Test of Water Purity.—Dr. Angus Smith, F.R.S., reports to the Local Government Board, as one of the inspectors under the Rivers Pollution Prevention Act, that in all natural waters sugar ferments and hydrogen gas is given off, the proportion varying with the organic impurity of the water. The proportion of hydrogen evolved will prove a quantitative test of the virulence of the microbes present in the waters.

University of Cambridge.—The Vice-Chancellor, Dr. Phear, Professors Paget, Latham, Humphry, Cayley, Liveing, and Foster, Mr. H. Latham, Trinity Hall; Mr. Coutts Trotter, Trinity; and Mr. D. Macalister, St. John's, have been appointed a Syndicate to take into consideration any Medical Act Amendment Bill which may be introduced into Parliament during the present Session, and to make such representations, and take such steps with reference therto, as they may think fit.

The Operations in the Red Sea.—Arrangements have been made for supplying Admiral Hewett's force with surgical and medical aid. About twelve surgeons will proceed from the Mediterranean fleet with the reinforcements supplied by the ships of the squadron, and, in addition, the surgeons of the Euryalus, Decoy, Ranger, and Sphinx, at Suakim, have been instructed to place themselves in readiness for service ashore with the medical officers who are on their way home from the East India station on board the Orontes. Medicinal stores will be supplied from the Mediterranean fleet, and from the head-quarters at Malta and Cyprus.

Donations to Hospitals.—A donation of 1,000*l.* has lately been presented to St. George's Hospital by an old governor. The sum was given after a minute inspection of the hospital as a mark of the donor's satisfaction with all he saw as to the condition of the wards and general comfort of the patients. Sir Massey Lopes, M.P., has contributed 1,000*l.* towards the erection of the South Devon and East Cornwall new Hospital buildings, being the third sum of the same amount he has subscribed during the past two years. There is still a deficit of 9,000*l.* The late Mrs. Dixon, of Belleisle, has left 1,000*l.* to the Ayr Hospital.

Naval Appointments. — Staff Surgeons — Frederick M'Clement, M.D., to the *Revenge*, *vice* Bolster; James H. Martin, to the *Euryalus*, for service with the Royal Marines in Egypt; William B. Drew, to the *Alexandra*, for service with the Royal Marines in Egypt. Surgeons—Michael J. McCarthy, M.D., and Nicholas C. Ross, to the *Alexandra*, for service with the Royal Marines in Egypt; James S. Wray, to the *Woodlark*, recommissioned; Henry W. D. Walsh, to the Plymouth Division, Royal Marines, *vice* Ross; Henry B. Collins, to the *Indus*, *vice* Walsh; Gilbert Kirker, to Haslar Hospital, *vice* Collins.

Royal College of Surgeons.—At a meeting of the Council on the 14th inst., Mr. Charles Atkin, L.R.C.P. Lond., of the Sheffield School of Medicine and Guy's Hospital, who passed his fellowship examination in May last, having since attained the legal age of 25, was admitted a Fellow of the College. his diploma of membership bearing date January 23rd, 1880.

The Bower and Keates Indemnity Fund.—The Committee have received a cheque for one guinea from Francis Willis, M.D., M.R.C.P.L., Asheville, N. Carolina, U.S.A., which was sent before the list was closed. All sums received since January 26th have been returned.

Erratum.—In the final list in the issue of Feb. 2nd, or "B. Harvey, Esq.," read "B. Harris, Esq."

F. A. Mahomed, R. W. Burnet, } *Hon. Secs.*

The Dublin Artisans' Dwellings Company.—The fifteenth ordinary general meeting of this company, was held on Tuesday, the 5th instant, Mr. Richard Martin, D.L., J.P., in the chair. Commenting upon the report, the chairman observed that the sanitary condition of the tenants of the company continued to be satisfactory. A population of 2,734 inhabited the various blocks of buildings in the City, and the deaths in the last half-year represented a mortality of 19·8 per 1,000 of the population annually. This figure was considerably under the general death-rate of Dublin. The deaths were 27 in number, of which, only one was from an infectious disease—scarlet fever, to which a child under five years of age succumbed. After providing for all expenses, there remained a net balance of 1,655*l.* 4*s.* 1*d.*, out of which the directors recommended a dividend of 4 per cent. per annum, leaving a balance of 254*l.* 1*s.* 10*d.*, to be carried to the reserve and depreciation fund.

Royal Institution.—Professor Arthur Gamgee, M.D., F.R.S., will give the course of five lectures on "Animal Heat; its Origin, Distribution, and Regulation," commencing on March 4th, instead of Professor McKendrick, who will probably lecture after Easter.

King and Queen's College of Physicians in Ireland.—At the monthly examinations for the licences of the College, held on Monday, Tuesday, Wednesday and Thursday, February 4, 5, 6 and 7, the following candidates were successful: For the *Licence to Practise Medicine*—Delahunt, William Patrick, Rathgar, Dublin; Finlay, Sinclair, Ballyshannon; Hazleton, Edward B., Holywood, Belfast; Manning, Nathaniel S., Ballyhaise, Co. Cavan; Peet, Francis Fitzmaurice, Tralee, Co. Kerry; Price, William Thomas, Fircapel, Brecon; Roe, Francis Christian, Mountrath, Queen's Co.; Smith, Ventry Alexander John, Sandycove, Co. Dublin. For the *Licence to Practise Midwifery*—Bell, Thomas Gillespie, M.D., R.M.I., Armagh; Brown, Henry Edward, M.D., R.M.I., Passage West, Co. Cork; Digby, Cecil Arthur, M.B. Univ.

Dubl., Dublin; Finlay, Sinclair, Ballyshannon; Hazleton, Edward Benjamin, Holywood, Belfast; Henderson, Robert Wilson, M.D., R.M.I., Garvagh, Co. Derry; Manning, Nathaniel Samuel, Ballyhaise, Co. Cavan; Peet, Francis Fitzmaurice, Tralee, Co. Kerry; Smith, Ventry Alexander John, Sandycove, Co. Dublin. The following Licentiate in Medicine of the College, having complied with the bylaws relating to membership, pursuant to the provisions of the Supplemental Charter of December 12th, 1878, was duly enrolled a member of the College:—George Deane Bourke, Lic. Med. 1873, Surgeon A.M.D.

APOTHECARIES' HALL.—The following gentleman passed the examination in the Science and Practice of Medicine, and received a Certificate to Practise, on Thursday, February 7th, 1884:—

Hillstead, Herbert Jno., Lewisham High-road, St. John's, S.E.

APPOINTMENTS.

APTHORP, FREDERICK W., M.R.C.S. Eng., L.R.C.P.—Medical Officer to the Manhood District, Westhampnett Union.

CLARK, C. A. D., M.B., L.R.C.P., M.R.C.S.—Honorary Physician to the Sydney Hospital.

DEVLINE, DR.—Medical Officer of the parish of Birsay, Orkney.

EMERSON, P. H., B.A. Cantab., M.R.C.S.E.—Sambrooke Medical Registrar to King's College Hospital, *vice* J. F. Silk, M.B., resigned.

GRITTITH, W. S. A., M.R.C.P., F.R.C.S.—Physician to Out-Patients, Samaritan Free Hospital.

HUDSON, C. L., L.R.C.P., M.R.C.S., L.S.A.—Resident Physician's Assistant to the Middlesex Hospital.

ILES, ALFRED R., M.R.C.S. Eng., L.R.C.P., L.S.A.—Medical Officer to the Workhouse, Taunton Union.

LARDER, HERBERT, M.R.C.S. Eng.—Assistant Medical Officer at the Infirmary, St. Marylebone Parish.

LITTLEJOHN, H. D., M.D., L.R.C.S.—Consulting Surgeon to the Royal Dispensary, Edinburgh.

LOANE, J., M.R.C.P., M.R.C.S.—Medical Officer of Health for the Whitechapel District.

MONTGOMERY, SAMUEL, L.R.C.P. Edin., L.R.C.S. Edin.—Medical Officer to the Ovenden District, Halifax Union.

PERRIN, WM. B. B., L.R.C.P. Edin., L.R.C.S. Edin.—Medical Officer to the Cameley District, and the Workhouse, Clutton Union.

PRICE, JOHN D., M.R.C.S. Eng.—Medical Officer to the Dudley North District, Dudley Union.

STEVENSON, T., M.D., F.R.C.P.—Re-appointed Public Analyst for the Borough of Godalming.

TOMKINS, ARTHUR W., M.D. Dub., L.R.C.S. Edin.—Medical Officer to the Leamington District, Warwick Union.

DEATHS.

BALFOUR, JOHN HUTTON, Emeritus Professor of Medicine and Botany in the University of Edinburgh, at Inverleith House, Edinburgh, on February 11.

BEALES, ROBERT, M.D., J.P., at Chapel House, Congleton, on February 3, aged 59.

ROY, J. J., M.R.C.S., at Humansdorp, South Africa, on January 17, aged 36.

VACANCIES.

BIRMINGHAM GENERAL HOSPITAL.—Resident Medical Officer. Salary £130 per annum, with board and residence. Candidates must be graduates in Medicine of a University, by examination. Applications, with certificates of registration or diplomas, and testimonials, to be sent to W. T. Grant, House Governor, on or before February 28.

NOTTINGHAM BOROUGH ASYLUM.—Assistant Medical Officer. Salary £100 a year, with board, apartments, and washing. Candidates must be duly qualified in Medicine and Surgery, and registered. Applications, with testimonials, stating age, &c., to be sent to the Medical Superintendent, on or before February 16.

SKIBBAUGH UNION, BRANDES BURTON DISTRICT.—Medical Officer. Area 10,430 acres. Population 1,472. Salary £24 per annum.

THE HOSPITAL FOR WOMEN, SOHO SQUARE, W.—Assistant Physician. —Also, Administrator of Anæsthetics. (*For particulars see Advertisement.*)

THE GENERAL HOSPITAL, BIRMINGHAM.—Resident Medical Officer. (*For particulars see Advertisement.*)

NOTES, QUERIES, AND REPLIES.

The Medical Services.—The following questions were set at the recent Examination of Candidates for Her Majesty's Army, Indian and Naval Medical Services:—

MEDICINE.—1. Describe the coarser or naked eye appearances, and the finer structural details or microscopic characters of the liver in the varieties of *cirrhosis* of that organ; and also in the so-called "*nutmeg liver.*" Discuss the causes, symptoms, complications, and sequelæ of the lesions you describe. 2. How do you estimate the following constituents in a clinical examination of the urine—(1) The amount of *solids* passed in the 24 hours, as approximately determined by the specific gravity of the urine? Give an example. (2) The amount of *free acid* passed in the 24 hours, expressing the result in the usual way? (3) The amount of *urea* passed in the 24 hours, determined by Liebig's method? (4) The amounts of *chloride of sodium* and of *chlorine* passed in the 24 hours? State the normal amounts passed by an adult man from 40 to 50 years of age, and 140 to 150 lb. weight, in the 24 hours, of—(1) *Urea;* (2) *Free acid;* (3) *Chloride of sodium:* (4) *Chlorine;* (5) *Water.* 3. Describe the structural changes which give rise to *regurgitant aortic valve disease.* Discuss the physical signs (including sphygmographic phenomena) of this condition, the consecutive results and the general treatment of a case. 4. Describe the distinguishing characters of the head, the mature joints and the ova of the *tænia solium, tænia mediocanellata* or *saginata,* and the *bothriocephalus latus;* and the sources of each of these parasites. 5. How do you diagnose the following diseases—*Ovarian dropsy, uterine fibroid or fibro-myoma,* and *large malignant tumour of the uterus?* 6. What are the medicinal substances which stimulate the liver? And discuss the evidences or reasons which justify the conclusion that the substances you name do so act.

SURGERY.—1. Mention the symptoms which would enable a surgeon to diagnose an irreducible inguinal hernia, not strangulated, from hæmatocele, and from an enlarged testicle. If the inguinal hernia be recent, not strangulated, but large and irreducible, what measures should be adopted with a view to its ultimate reduction, without recourse to operative interference? 2. What are the various causes of blood in the urine, independent of accident? Describe the symptoms which would indicate whether it depended on kidney, or on bladder complications. 3. A patient has obstruction of bowel. Describe the symptoms which would indicate that the seat of obstruction was probably in some portion of the small, rather than in the large bowel, and the treatment in such a case. 4. Describe the conditions diagnostic of epithelioma of the tongue; the symptoms which would indicate the propriety of operation, and what would be the best method of its removal. 5. What is the condition known as perforating ulcer of the foot; to what cause is it ascribed and what should be the treatment? 6. Under what conditions does a mammary abscess most commonly occur; what are its usual symptoms, and what should be the treatment, local and constitutional?

ANATOMY AND PHYSIOLOGY.—1. Describe the occipital bone, and let your account include a description of its articulations, its relations to other parts of importance, and an enumeration, in in their order, of muscles or other tissues to which it gives origin or insertion. 2. Describe the anatomy of the male perineum, enumerating, in their order, the parts exposed in a dissection of this region. 3. Describe the pancreas, its position, anatomical relations, structure and physiological functions; give an account of its secretion and its effects on digestion. 4. Describe the origin, course, anatomical relations, and distribution of the right vagus nerve and of its branches. Give an account of its functions generally, and especially of those of the branches which are distributed within the thorax. 5. Describe the dissections by which you would expose the cervical portion of the internal carotid artery, and the relation that it bears to surrounding parts.

ZOOLOGY, BOTANY, AND PHYSICS.—*Zoology:* 1. Select any form of Echinodermata you please, and describe the more important points in its structure. 2. To what sub-kingdom and class of animals do we owe the formation of coral reefs? Give a classification of coral reefs, and mention the principal features in their geographical distribution. 3. Define the term "Notochord," and adduce one or more examples of the persistence through life of this structure? 4. What is meant by "alternation of generations?" Cite from the animal kingdom one or more examples of this phenomenon. 5. What are the special features by which the mammalian fauna of the Australian region is characterised? *Botany:* 6. What are the conditions necessary for the germination of the seed? 7. Give some examples of underground stems, and show how these differ from true roots. 8. What is the "Cambium layer" in a dicotyledonous stem? Describe the behaviour of this layer during successive years in the growth of such a stem. 9. Point out the differences between the germination of a bean and that of a grain of wheat. 10. Contrast with one another, as regards the condition of their floral verticils, the following genera—Lilium, Papaver, Primula. *Physics:* 11. Define electrical induction, and point out the essential nature of this phenomenon, 12. Describe some of the modes by which a bar of steel may be

converted into a magnet. 13. Describe an experiment for showing the composition of water by means of the voltaic current. 14. Explain the origin of the tides, pointing out the conditions on which spring and neap tides, respectively, depend. 15. What is a moraine? Enumerate and distinguish the various kinds, and point out the origin of each.

The Paris Bibliothèque Nationale.—According to the inventory of the Paris National Library, which has just been completed, the number of volumes at the present time amounts to 2,500,000. The manuscript cabinet contains 92,000 volumes either bound, stitched, or in boxes, and 144,000 medals of all epochs, both French and foreign. The collection of prints amounts to more than 2,000,000 specimens, either bound up in 14,500 volumes, or in 4,000 portfolios, the most precious of these being deposited in the reserve gallery, to the number of 80,000. The National Library is in fact the richest and the oldest of all European libraries; and one may judge of progress of intellectual movement of late years in France by the fact that while there were but 24,000 readers in 1868, these had risen in number to 70,000 in 1882.—*Revue Scientifique*, January 26.

Dr. Harris.—The discussion on Mr. Erichsen's motion, in which you in common with so many Fellows are so much interested, came on at a meeting of the council yesterday.

A Country Member.—The Hunterian oration is now a *biennial* discourse. Our advertising columns will give you the desired information.

Dr. Dey, Calcutta.—Letter and Enclosure received with thanks.

COMMUNICATIONS RECEIVED—

Sir James Paget, Bart., London; Dr. Roche, Kingstown; Mr T. P. Peek, London; Dr. Granville Bantock, London; Dr Tirard, London; Dr. Clifford Beale, London; Dr. Willoughby, London; Dr. Shelly, Hertford; Dr. A. Hughes Bennett, London; Dr. G. Coates, London; Dr. Herman, London; Mr. J. Hutchinson, F.R.S., London; Dr. Mercier, Dartford; Dr. Burckhardt-Merian, Basle; Mrs. Lankester, London; The Secretary, Apothecaries' Society, London; Mr. Hughes, Liverpool; The Secretary, Charing Cross Hospital; The Secretary, Royal College of Surgeons, Edinburgh; Dr. Ewart, London; The Director-General, Army Medical Department; Mr. T. Duxbury, Blackburn; The Registrar-General, Edinburgh; Mr. T. Stone, Wimbledon; Dr. W. J. Branch, St. Kitts; Dr. W. Blyth, London; Dr. H. APPOINTMENTS FOR THE WEEK.

February 18. *Monday.*

Medical Society of London.—Drs. Coupland, Bristowe, Cayley, and Frederick Taylor, will read Papers embodying "The Results obtained in the London Hospitals by the Cold Bath Treatment of Enteric Fever." The subject will be continued on February 25th. Mr. Fleming will show a Surgical Lamp Battery in the Library. Dr. Sansom will show specimens of Solid Liniments.

Royal College of Surgeons of England, 4 p.m.—Prof. W. K. Parker, F.R.S., will deliver his Seventh Lecture "On Mammalian Descent."

19. *Tuesday.*

Pathological Society of London, 8.30 p.m.—Dr. Angel Money, "Spinal Cord, from a recent and old case of Infantile Palsy." Dr. Coxwell, "Amyotrophic Lateral Sclerosis." Dr. Sainsbury, "Malignant Disease of Mesentery." Dr. Norman Moore, "Interstitial Disease of Ovary." Dr. Hobson, "Secondary Nodules on Peritoneum in a case of Ovarian Tumour." Mr. Watson Cheyne, "Two cases of Purpura Hæmorrhagica in which Organisms were present." Mr. Barwell, "A Neoplasm affecting the knee-joint." Mr. Lane, "Fracture of Cartilage of the first rib." Dr. Hall White, "Insular Sclerosis." Mr. Dent, "Deformity of Feet from Perforating Ulcer" (living specimen). Mr. Shattock, "Double Vena Cava, the left being the larger" (card).

Royal Institution, 3 p.m.—Prof. A. Geikie, "Scenery of the British Isles."

20. *Wednesday.*

Royal College of Surgeons of England, 4 p.m.—Prof. W. K. Parker, F.R.S., will deliver his Eighth Lecture "On Mammalian Descent."

21. *Thursday.*

Royal Institution, 3 p.m.—Prof. Pauer, "Music for the Pianoforte," &c.

22. *Friday.*

Clinical Society of London.—The following Papers will be read:—Mr. Mansell Moullin, "A case of Thrombosis of the Vena Cava;" Mr. R. Clement Lucas, "A case of Charcot's Joint Disease;" Mr. Noble Smith, "A case of Dislocation of one of the Semilunar Cartilages;" Dr. Samuel West, "A case of Multiple Hepatic Abscesses in a Boy." The following Living Specimens will be exhibited:—"A case of Excision of the Patella, by Mr. R. Clement Lucas; "Anomalous Affection of certain Bones and Joints," by Mr W. Morrant Baker; "A case of Nodules on the Finger," by Mr Godlee.

Royal Institution, 8 p.m.—Sir F. Bramwell, "London (below bridge) N. and S. Communication."

Royal College of Surgeons of England, 4 p.m.—Prof. W. K. Parker, F.R.S., will deliver his Ninth Lecture "On Mammalian Descent."

23. *Saturday.*

Royal Institution, 3 p.m.—Prof. Morley, "Life and Literature under Charles I."

CASES OF SPINAL DISEASE, ILLUSTRATING THE CLINICAL HISTORY OF SPINAL SCLEROSIS.

By JAS. RUSSELL, M.D., F.R.C.P.,

Physician to the Birmingham General Hospital.

I present a report of certain cases of paralytic disease of the spinal cord, on account of the illustration they afford of that form which is associated with the symptoms (spasmodic contraction, tonic and clonic, and tremor) with which pathologists have been taught by experience to connect the idea of sclerosis of certain parts of the cord; but which still leave some fundamental questions respecting the pathology of the diseases either imperfectly answered, or altogether waiting to receive a reply. To these cases, in order to point the contrast, I add a case of amyotrophic lateral sclerosis, together with a typical instance of the malady originally known as infantile paralysis, appearing in the adult. I may at once say that I have only a clinical report to present; I have not enjoyed the rare opportunity vouchsafed to Dr. Dreschfield, of verifying a diagnosis by the conclusive evidence of post-mortem examination.

The spasmodic element in these diseases possesses a pecial interest for some of the older generation of students of medicine like myself, on account of the association, in its tonic form, with the name of an original and close observer, and an admirable clinical teacher, the late Dr. Todd, who, in his "clinique," often laid much stress on the forms of rigidity which are apt to occur as a secondary condition, in limited cerebral disease, and which he classed under the terms of "early and late rigidity." More than one theory, besides that formulated by Dr. Todd, was offered to explain this occurrence, previous to the observations of Türck, observations with which the public are now acquainted, as expanded by Charcot and Erb.

The principal symptoms of sclerosis of the lateral column of the spinal cord are represented by Erb ("Ziemssen's Cyclopædia," xiii., 622) as having been combined from various complicated cases; these have been expanded by himself and by Charcot—by the latter especially, in his "Lectures on Localisation in the Spinal Cord," lately published by the New Sydenham Society. In these lectures a disease picture of Secondary Sclerosis (uni-lateral) of the Spinal Cord is ably constructed, from cases of limited cerebral disease, like those observed by Dr. Todd. From these instances the argument is applied to cases of similar spasmodic paralysis, secondary upon spinal lesion implicating the entire thickness of the cord, and attended with destruction of the white fibres in a limited area. The degeneration is a consequence of this destruction of tissue.

I shall narrate two cases illustrating this secondary form, consequent on spinal disease: one of the cases exhibiting the clinical change in its early stage of gradual development; the other in its completed form; the two cases presenting interesting differences between themselves, such as are met with in any collection of examples of this form of disease. In each instance evidence of incapacitating lesion having preceded the spasmodic symptoms is very clear.

Considerable interest, however, extends beyond these cases of secondary spasmodic paralysis, whether of cerebral or of spinal origin, to another class in which no lesion can be ascertained to have existed prior to the appearance of the spasmodic paralysis, in which, therefore, the question has to be considered whether or not the spasmodic disease is of primary and independent origin; and if so whether it consists in the same condition of the lateral columns as we find in the cases I have just quoted.

With respect to the spasmodic contraction which constitutes the distinguishing feature in lateral sclerosis of a secondary order, this is referred to irritation communicated to the spinal motor cells from the sclerosing pyramidal columns, these cells standing between the morbid process in these columns and the roots of the nerves. Whether, and to what extent, another element may have a share in the production of the spasm, viz., the separation, by the change in the pyramidal columns, of the spinal cord from the controlling influence of the brain, it is not now necessary to enquire, nor is it necessary to discuss the enquiry, closely allied with the last-mentioned question, and ably analysed by Dr. Bastian in *Quain's Dictionary of Medicine* (article, "Spinal Cord, Diseases of") as to the nature of the sclerosis itself, whether it is to be regarded as being of necessity inflammatory in its origin. Charcot emphasises the statement that the lesion thus communicated to the motor cells, is dynamic only, unaccompanied by any ascertained material change. The motor cells, in fact, constitute the element opposing the degenerative process in the grey matter, and preventing it from reaching the nerve tubes and the anterior roots. Once established, however, the dynamic influence extends through the nerve reticulum, causing the reflex phenomena which form so prominent a feature, by exaggerating the effect "of those permanent stimuli which ordinarily emanate from the muscles and their aponeuroses."

This condition of exalted reflex irritability, as pointed out by Charcot, may arise quite independently of any organic lesion. It is closely connected with spinal sclerosis, co-existing therewith as a rule; it is, nevertheless, contingent, and not "a function" of that lesion: it may arise independently. It does so arise in strychnine poisoning; and hysteric contraction is a typical illustration of its independence. I may quote briefly a striking evidence of spasmodic contracture having all the character of the contraction of spinal sclerosis, and occurring, moreover, in union with symptoms which completed the picture of secondary spastic paralysis, in which, however, there could be no doubt as to the absence of organic change in the spinal column. The case was published in this journal, January 24, 1880. Prior to experience of the course of the case, it was naturally set down as a case of secondary spastic paralysis, possibly of sclerosis, of secondary origin, until complete recovery after several months' duration of the disease, and its return, to be again dissipated, entirely negatived the correctness of the first diagnosis. The complete suspension of tactile sensibility, and of the expulsive function of the bladder at the beginning of each attack, recalled the usual course of secondary sclerosis, though the rapidity with which the symptoms were renewed threw great doubt, at a later period, on the supposition. I regarded the symptoms as probably dependent on disease of the intervertebral cartilage, founding my suspicion on the obvious influence of the upright posture in encouraging the relapse, and supporting the suggestion from Mr. Aston Key's paper in Guy's Hospital Reports, 1859, and by a case from Dance, reported by Ollivier (*Maladies de la Moelle Epiniere*, ii. 326). I may take this opportunity of supplementing my report of the case by stating that the patient continues in good health.

The question respecting the primary origin of spastic paralysis relates to a different order of circumstances. It was raised by Erb in 1875; it was developed by Charcot in *Le Progrès Médical*, November 4th, 11th, and 18th, 1875, and has been again brought forward in his Lectures, recently translated. It is of course conceivable that the condition in question may result from some disease outside the pyramidal tract; but excluding doubtful examples, attention is drawn by Erb and by Charcot to a group of cases, which, in the first place, exhibit a feature at once placing them in a position by themselves, viz., that no symptoms could be discovered pointing to antecedent lesion in the brain or cord. Another phenomenon belonging to these cases, was the limitation of the symptoms, from first to last, to those referred to the motor region of the cord — "this isolation, especially," says Charcot, "whence results the monotony of the clinical picture so special to the malady, should be regarded as an element of the first order." The cases, too, are distinguished by their chronic character, by their slow evolution (extraordinarily slow in development, and very chronic in course, states Erb), and by a disposition to ascend, involving first the muscles of the abdomen and loins, and finally those of the upper extremities. The health of the patient remains good; according to Erb, the disease is met with most frequently in the robust and strong, and in those not subjected to any neuropathic influence.

The pathological foundation for the group, as a distinct class, Erb believed to exist in sclerosis of the lateral columns of primary origin; "if contrary to our expectations, the opinion shall prove to be false, the disease here to be described, would nevertheless remain as an independent, well characterised form of disease, and we should still have to search for the symptom picture of sclerosis of the lateral columns." Charcot's position is the same of that of Erb, each waiting for post-mortem examination to verify or contradict the opinion. The final verification has been furnished by Dr. Dreschfield, who has at last, by anatomical evidence, settled the question of the existence of such a disease as primary sclerosis of the lateral columns, thus far justifying the prevision of the authors I have quoted.

An obvious difficulty in establishing the diagnosis from clinical signs alone, in cases of primary lateral sclerosis, consists in the necessity of clearing the case from all probability of a dependent origin, on some pre-existing lesion; and the possibility of slowly advancing obscure disease has to be considered. Nor must it be overlooked that the originating lesion may be intracranial. Accordingly, Dr. Gowers ("Diseases of the Spinal Cord," p. 47) observes that primary degeneration of the lateral columns, limited thereto, is extremely rare, and the diagnosis can only be justified when no evidence of a wide focal lesion can be obtained, and when this affection has come on very gradually. Dr. Bramwell's position ("Diseases of the Spinal Cord, p. 216) towards the question is the same.

Cases of a chronic character, with symptoms developing very gradually, often do not come under observation until a late period, and thus we have to rely, in a great measure, on the history given by the patient, which is too often wanting in the information most needed for forming a safe opinion. My first case illustrates this difficulty, though the account appears

tolerably clear; if it be, indeed, a case of primary sclerosis, it exhibits the disease in its most characteristic form. The healthy condition of the patient, the gradual progress of the symptoms, the commencement apparently in a paretic condition of the muscles, in fatigue and heaviness of the limbs, and in difficulty of raising them from the ground, together with absence of important evidence of prior disease, agree with the general description of the malady. The reflex phenomena in the patient present a feature of interest. They represent the condition of the central organ from which the stimulus to contraction emanates, as one of incompetence to maintain the effort of the organ made to obey the excitement conveyed to it. Sustained excitement, as by the continuous current, or by exposure to the atmosphere, resulted in a series of alternate muscular contractions and relaxations effected with considerable rapidity; the movements were, in effect, a kind of clonos executed slowly and on a large scale, and afforded an interesting illustration of the nature of clonos and of tremor. As regards the cause, it appears not unlikely to be found in the frequent exposure of the lower extremities to the influence of cold and wet, at the time they were undergoing long-sustained exertion.

Case 1.—*Primary* (?) *Lateral Sclerosis.*—W. W., aged 41, married, was admitted into the Birmingham General Hospital, April 18th, 1883. He was a country postman, and had been in this employment for twelve years. It was his business to walk sixteen or seventeen miles per day, and six or seven on Sundays. He felt fatigued by the labour, but never was laid by. He was exposed constantly to a chance of getting wet on his round; his waterproof cape directed the rain which fell upon it to his legs, and then his trousers were often kept wet through the day; but he never had rheumatism, nor had he failed in health.

When admitted he had been compelled to leave his occupation for more than three years by inability to walk; but during the twelve months preceding these three years his walking had gradually become more difficult through "his legs becoming weak and from their stiffening." When questioned particularly respecting the nature of his difficulty, he stated that it was gradually increasing stiffness in his legs, which disabled him; the legs were very stiff when he got home at night, after sitting down it was difficult for him to get up again; his toes dragged on the ground in walking, and he was a great deal longer about his work than he used to be. First his legs began to ache and to feel stiff, they kept aching worse and were very tired; it took him a deal longer to get along the ground. The legs gradually grew stiffer from the time when they began to ache. He had neither pain, startings, nor tremors, it was simply the stiffness of which he complained. He has not walked for twelve months, though at present he can just reach the closet near his bed by help of the bed posts. He had no difficulty in passing urine until the last twelve months, when he has been compelled to wait two or three minutes before his water made its appearance. There has been no other fault in micturition. He has been quite free from pain in his back.

His health has been good; his habits sober and regular. He absolutely denies ever having suffered from any form of venereal disease; nor can any evidence to the contrary be obtained. The family history is quite free from any evidence of hereditary tendency except that his mother died of cancer.

I found him wearing the aspect of a robust well-made muscular man; he was lying on his back, with knees half bent, though subsequently, during his stay in the hospital, they were usually found in extension, the ordinary position in these cases. The lumbar muscles were strongly contracted, arching the back and quite raising it from the bed. Notwithstanding, however the restrained condition of his joints, he was still able to effect a small amount of movement in his lower extremities; thus he could raise his limbs from the bed; when the knee had been passively flexed, he extended it with considerable force; and he had some, though very limited, control over his ankle. The muscles of the lower extremities were generally in a state of tonic contraction, firmly resisting all movement at the joints; but there was a certain difference in the degree of contraction. It was the ham-string muscles which exhibited the rigidity in its highest degree; they were rendered by it of stony hardness, and their tendons were converted into tense cords. The adductors of the thigh were scarcely inferior in this respect to the ham-strings, it being scarcely practicable to separate the thighs; the resistance in the other muscles could be overcome. The anterior muscles of the thigh, again, were less tense than those just described, and the muscles of the calf were quite soft, though so easily thrown into contraction that the movement of the ankles was very limited. The lumbo-dorsal muscles were perfectly tense, and those of the abdomen also, though to a less degree. By no effort could the lower ribs be brought to expand beyond ¾ inch; the diaphragm acted freely. The muscles of the shoulder and neck were completely spared. No relaxation in the rigidity was observed during sleep, and the patient's personal experience confirmed the correctness of this statement. The nutrition of the muscles was excellent.

Muscular irritability was much exalted in the affected regions: when the lower limbs were first exposed to the air, they entered upon a succession of gentle flexion and extension movements. The same effects followed attempts at passive movement or handling the muscles, or tickling the soles of the feet; even contact with the points of the compasses, in testing sensibility, produced the same acts. All the phenomena were exhibited more fully on the left than on the right side.

The reflexes presented considerable departure from the arrangement ordinarily observed, as if from removal of the limitation which directs any irritation into a special channel. The tense condition of the muscles of course prevented the production of clonos, and mostly of the knee jerk; but a slight indication of the latter movement was present occasionally. Generally slow extension of the knee followed a tap on the patellar tendon, and the same effect resulted more rapidly from striking the flexor muscle of the knee, by tapping the extensor muscles, or by irritation of the cutaneous surface of the thigh. Plantar reflex was very active, but was manifested by flexure of the knee, and a hot spoon applied to the sole, was followed by the same result. A tap on the front of the left thigh raised the heel; one on the front of the right leg, flexed the ankle.

Cremaster reflex could not be produced; abdominal reflex was probably interfered with by the rigid condition of the abdominal muscles.

Electrical reaction (continuous current) manifested considerable effect by ten cells. By a strong continuous current of 29 cells, the cathode being applied to the thigh, flexion and extension of small extent at a rate of 60 per minute immediately took place; the same effect followed the application of the rheophore to the leg. With five cells a few imperfect contractions were all that ensued.

Much the same effect was produced by the employment of the Faradic current.

The channel of sensation, as in the case of the reflexes, seemed deranged. Touch on the left thigh was referred to the right, and on the right leg was referred to the leg on the opposite side. A hot sponge

*

was not recognised on the left thigh; it felt cold on both legs. Cold was not distinguished as cold, on the left leg, and imperfectly on the right. There was no disorder in the function of urination. The spinal column was quite healthy to smart striking and no particular effect followed the passing of a hot sponge down its length.

It was a strange thing that having suffered for four years, he had never applied for treatment.

Priestley Smith reported a little haziness at the margin of the discs, and streaks along the vessels. The pupils were normal.

Urine was normal and so were all the internal organs. I tried the effect of scoring the back with the hot iron, but with no beneficial result. Iodide of Potassium, Bromide, and Belladonna, were alike useless. The two latter not even causing temporary relaxation of the spasm.

(*To be continued.*)

A CASE OF HYDROPHOBIA.

By H. H. CLUTTON, M.B., F.R.C.S.,
Assistant Surgeon to St. Thomas's Hospital.

For the notes from which the account of this case is written, we are indebted chiefly to Mr. Thomson and Mr. Cooper (the House Surgeon) who, with other qualified dressers and resident officers, were unremitting in their care and attention whilst the patient was under the influence of chloroform. And for the previous history of our patient, with the interesting details concerning the dog and cats, we are especially indebted to Dr. Bligh.

Mary J., single and in service, æt. 43, was admitted into St. Thomas's Hospital on Sunday, September 23rd, 1883, with the following history.

About the middle of last May, between four and five months ago, she was bitten on the wrist by a cat. Her friends gave the following account of this accident. She went into a house to call on some friends, and saw a cat lying crouched beneath a ladder. At all times fond of cats, she was stooping over to stroke it, when her friends begged her to leave the animal alone, saying it was mad. She, however, declared that it was ill, only because it had been starved, and did as she was warned not to do. The cat immediately flew at her, and was seen hanging from her wrist. The wound was cauterised by a chemist, and when it healed, which it did in a few days, she and her friends thought no more about it, judging that then all danger was past.

The history of rabies in the cat is as follows:—In the January preceding (1883), a strange, ill-conditioned dog had been received into the house, and two months afterwards had been destroyed, for what was thought to be rabies. He refused his food, began to snap at the feet of the family under the table, and although he continued to make great demonstrations of affection towards his master, he eventually growled and snapped at him, and was forthwith destroyed. There were, also, two pet cats in the house, and within a few weeks of the dog's death, one of them showed similar symptoms, refusing food, appearing ill, and spitting at her best friends. This cat was driven away alive, and has never been seen or heard of since. Early in May, the second cat was similarly affected, and bit our patient as described above. None of the animals were known to have been bitten by the other.

Our patient is described as being a hard-working, sensible woman, never at any time subject to illness of any kind, and not, as far one can judge from description, in the least hysterical. After the wound had healed, she remained in perfect health, doing her work till about ten days before admission into the hospital. About this time she felt some pain in the right arm, shoulder, and neck, which she attributed to rheumatism, but it troubled her so little, that she made no complaint, and went on as usual with her work till four days before she was sent to the hospital. In the evening of this day, which was Wednesday, she went to a chemist, who gave her some pills and medicine. On taking the medicine the next morning she first experienced difficulty in swallowing. This difficulty she described as a sudden current of air taking her breath away, and preventing her swallowing. On the two following days, she continued to do some of her work, but found that she could not take any fluids. Bread soaked in milk formed her chief diet, and this could be easily swallowed. She gradually became worse, and on Sunday morning, the day of her admission into the hospital, she was taken by her mistress in a cab to her friends. On the way she was seized with terror, crouched down on the floor of the cab, grasped her mistress's knees, and screamed out something about the lunatic asylum. Dr. Bligh saw her with her friends at two p.m., and found her sitting up in bed quite quiet and composed. She complained to him of her throat, saying that she could not swallow, although she was intensely thirsty. She stated also that her right arm and shoulder were very painful. After examination of mouth and throat, Dr. Bligh offered her a glass of water. She took it quite willingly in her hand, the sight and sound of water not affecting her in any way. But when she had steadily raised it to her lips, there was a convulsive gasping for breath, and a long deep-drawn inspiration. She exhibited no terror and talked quite calmly about it immediately afterwards. The relatives were then taken into another room, and questions were asked, which led to the story of the mad cat.

Before Dr. Bligh made these enquiries, no one had suspected the cause, so distantly removed, as they thought, from all her trouble. Care was taken, both then and subsequently, that she should not be informed of the supposed cause of her condition, so as, if possible, to keep her mind free from this anxiety. She had never herself alluded to it since the healing of the wound, and was, apparently, quite unaware of any connection or possible relation between the two circumstances. Dr. Bligh, after his examination, ordered her instant removal to St. Thomas's Hospital, where she arrived on Sunday evening, September 23rd.

At ten p.m., a few hours after her admission, I found her in a small ward, sitting up in bed. Before I had time to ask her any questions, she seized me by the coat with both her hands, and begged and prayed me to help her. She then suddenly jumped forward, as if about to turn a summersault, with her head buried in the bed-clothes, clutched violently at the counterpane, and then suddenly threw herself backward, grasping her throat with both hands. These movements were evidently quite voluntary, but apparently done in a kind of fury, as if the person were angry with herself. When asked to explain what all this meant, she repeated several times in a petulant kind of tone, "It won't pass." When urged again to explain what she meant, she said, "The spittle, of course." All this was done in an irritable kind of manner, which can be only feebly expressed on paper. As soon as the paroxysm was over she talked quietly and rationally, described the pain she had had in her arm, and her inability to swallow. When asked if she had been bitten by a cat some months ago, she answered, "Oh, yes! but it has nothing whatever to do with this difficulty of swallowing. It has been healed a long time."

She asked to be allowed to have something to drink, but as soon as it was brought she turned away from the glass with most unmistakable horror. She

insisted upon having a little water so that she might not see it. Finally, after many pauses and renewed efforts she seized the glass, almost tossed the water into her mouth, and as suddenly threw the glass away. A paroxysm immediately ensued, preceded by a deep-drawn gasping inspiration. But after a little while she quieted down, and was evidently pleased that she had managed to take the fauces by surprise.

It seemed, if one may attempt to explain this peculiar condition, that whenever she tried to swallow even her own saliva and so moisten the throat, which was exceedingly dry and parched, the ineffectual efforts to do so worked her up into a perfect frenzy, which showed itself in these passionate movements—for none of them could be called spasms or even convulsive attacks, but rather the paroxysms of rage that might be seen in a maniacal patient.

The next morning (the 24th) I found that the nurse on duty had been obliged to send for help, as she could not, single-handed, keep the patient in bed. She had been more constantly violent, throwing herself about in such a manner that without timely aid she would have bruised and injured herself severely. As soon as I approached the bed she was loud in her abuse of all her attendants, saying that they were cruel and brutal, taking no notice of her sufferings and not attempting to relieve her. The paroxysms of frenzy (for it is difficult to give them a more definite name) were now succeeding one another with great rapidity, leaving only a minute or two between each attack. Her mouth was full of saliva which hung from her lips in long viscid strings, and formed one of the most distressing sights I have ever seen. She had apparently ceased to attempt to swallow any fluid, although she constantly asked for water. But as soon as it was brought it was rejected. I doubt very much whether at this time there was even any effort made to swallow her own saliva. Probably the total inability to do so prevented her from attempting it. The extreme sensitiveness of the lips was most remarkable. She could not bear to have the ordinary earthenware spittoon brought near her. It invariably induced a violent paroxysm. She preferred to try and spit into a handkerchief, but frequently this was impossible, the viscid saliva hanging from her lips in such a manner that it could not be removed except by being wiped away. She would allow no one to do this for her, and often waited some minutes to summon up courage to do it for herself. She then seized the handkerchief, and with one determined effort drew it rapidly across her mouth, and in the same movement of the hand threw it violently from her. A deep gasping noisy inspiration followed instantly upon this application of the handkerchief, whilst she fell back struggling with herself and with her attendants. In the intervals between these paroxysms, she was perfectly rational in her remarks, but despondent. She felt sure she must die as she could not swallow, complained bitterly of her fancied ill-treatment, and was angry and irritable with all her surroundings.

As it was evident that the disease was so far advanced that she must shortly be worn out by these constantly recurring paroxysms, and the total absence of any nourishment, I determined to give chloroform, for the purpose of feeding, and, if she bore it well, to keep her more or less under its influence as long as it seemed desirable. This treatment was commenced at 1 p.m. on Monday the 24th, and a pint of fluid nourishment introduced into the stomach by the soft œsophageal tube. In order to reduce, if possible, the amount of chloroform necessary to keep her quiet, she had 60 grains of chloral given by the rectum. The chloroform was then only administered when the patient showed signs of returning consciousness. A qualified man sat by the bedside and watched for these signs. As the pupil began to dilate, he found the consciousness began to return, and a few whiffs of the anæsthetic quickly made her again insensible to surrounding circumstances. Thus there was never any struggle to get the patient under its influence, such as there was in the first instance, for she was never allowed to return completely to herself. She was fed again with a pint of nourishment at 4.45 p.m., and given 60 grains of chloral by the rectum. Between this time and 9.25 p.m. she required chloroform twelve times, but administered only for two or three minutes; she consequently had it about two or three times in the hour. Nourishment was again given by the tube, but the chloral was omitted, as it seemed to have done its duty. At 12.30, three hours after the last feeding, the œsophageal tube was used again for a pint of fluid nourishment, and chloral, 60 grains, was administered by the rectum. She had had chloroform ten times between 9.30 and 12.30, and for an average duration of one-and-a-half to two minutes. She slept after this for one hour and a half, and between 12.30 and 5 a.m. only required chloroform five times, but the length of administration was on the average from three to five minutes. The reason of these long intervals of freedom from chloroform, and longer administration when it was given, appears to have been the fact that the patient slept a great deal. Her condition was at this time a great contrast to that of the previous night, which was passed in most violent excitement.

At 5 a.m., September 25th, nourishment was again given by the œsophageal tube, and the urine, which had not been passed naturally since chloroform had been commenced, was drawn off. After this she slept till 6 a.m., when chloroform was given for five minutes; at 6.45 she started up suddenly and began to struggle violently, chloroform was given again for five minutes, and altogether, from 5 a.m. till 10 a.m., the chloroform was repeated ten times, varying in duration from two to five minutes. Her return to consciousness was on each occasion much more sudden, and she occasionally struggled violently and spat about the bed before quiet was restored.

At 10 a.m. a pint of nourishment was again administered, by the œsophageal tube, but a small quantity for the first time returned. She was quite quiet after this till 1.15 p.m., requiring no treatment of any kind, when she suddenly started up and tried to get out of bed. Becoming more and more restless and excited, chloroform was given at 1.30 p.m.; but the pulse became irregular and intermittent, and finally almost stopped. After trying several times with the same result, the chloroform was discontinued. She still seemed partially under the influence of some anæsthetic, probably chloroform and chloral combined. An attempt was, therefore, made to moisten her lips with a teaspoonful of milk. The mere contact of the spoon with the lips, although the patient was apparently at that moment quite unconscious of her surroundings, produced the characteristic deep-drawn inspiration, which always preceded the irregular movements before described. As chloroform could not be borne, and we wished to feed the patient as before, she was put under the influence of ether at 2 p.m., and a pint of fluid nourishment poured into the stomach by the œsophageal tube. Very little of this returned. During the afternoon she was occasionally made to inhale ether, but only to restrain her from violent movements. Again, at 7 p.m. nourishment was administered in the same way. Two or three ounces were rejected by vomiting. From 7 p.m. to 10 p.m. ether was given for a short time, at intervals of twenty minutes, when it was discontinued entirely. It appeared as if the patient had a general delirium from the anæsthetic, and a good deal of fluid in the bronchial tubes.

The question now arose, whether an anæsthetic should be given for the purpose of feeding, and if so, in

what form. I thought possibly the chloral might have produced the intermittent pulse before observed, and as I was quite determined to feed the patient every four hours, it seemed better to again try chloroform, which had at first answered so well. At 11 p.m. I began to administer the chloroform myself, and I must say the pulse "jumped about" in the most alarming manner, especially when the anæsthetic was pushed far enough to give the patient a pint of fluid nourishment. Consequently, orders were given that, as far as possible, except for the purpose of feeding, neither ether nor chloroform was to be administered. The patient was muttering the greater part of the night, occasionally struggled, and attempted to bite the hands of those that held her, but there was no approach to the violent excitement observed on the first night of admission, and she passed a considerable part of the time in quietness and peace.

At 5 a.m. (September 26th), the food was poured into the stomach as before under chloroform, but on this occasion, and for the first time, it was almost entirely rejected. From this date to her death 30 hours afterwards, there is little to record, each time she was fed the food returning by vomiting. When the bowels had been cleared out, nutrient enemata were given and retained at first, but after the first two these also were rejected. Chloroform had to be given for this purpose, but it could not be continued as before on account of the extreme irregularity of the pulse which immediately ensued on its administration. When consciousness returned, she frequently prayed to be put out of her misery, became extremely restless and almost violent, throwing herself back with the spine arched, then jumping up and trying to get out of bed. She showed a good deal of strength, although her struggling movements were not so long continued as before. There was nothing in the nature of a spasm, except perhaps the deep-drawn "catching" inspiration which was always observed whenever the lips were touched, and seemed quite a reflex phenomenon. Later in the day these paroxysms of restlessness began by twitching of the eyelids, rolling the head from side to side, followed by the same rhythmical kind of movement in the forearm, and finally the attack or paroxysm terminated by a wildly violent struggle in which the patient had to be kept in bed by force. But still none of these movements could be called spasmodic or convulsive. As these attacks seemed to increase and gave rise to great distress, chloroform was again given in the evening, and continued through the night whenever the struggles became excessive. It never produced the same continued calming effect as when chloral was being simultaneously given, but whether this was due to the action of the drug or the different stage of the disease, it is difficult to say.

It was impossible to give chloral with the same certainty as before. A dose (gr. xxx) was introduced into the rectum, with each nutrient enema, but the first only was retained, and the dose was small. They were subsequently returned within half-an-hour of their introduction. It was evident now that nothing was retained by the mouth or the rectum, that all one could do was to relieve her sufferings till she died. Certainly chloroform seemed the most humane treatment. Consequently, it was allowed to be given through the night, in sufficient quantity to keep her absolutely quiet. In three and a quarter hours fourteen drachms, by measurement, were given, and during this time the pulse remained regular and of fair strength, suggesting most strongly that the previous difficulty in its administration—namely, the condition of pulse—was due almost entirely to the chloral, for by this time the effects of the latter had had time to disappear; but, on the other hand, very little chloroform was then required to keep her quiet, whereas now she had a large quantity continuously administered. It was given on lint, so that the dose above stated must not be taken as the real amount inhaled, and one knows, too, how much more wasteful some men are than others in this method of administration. It is only quoted to show that chloroform was required in a large quantity and continuously, before it produced the same effect as when first administered in conjunction with chloral.

She died the next morning at 10 30 a.m. (September 27th), apparently from exhaustion. The struggling had ceased, and chloroform was not being given.

LIFE AT SEA—MEDICALLY CONSIDERED.

By A. HUGHES BENNETT, M.D.,
Assistant Physician to the Westminster Hospital.

It is customary with many physicians to recommend their patients, under certain circumstances, a sea voyage. This they do in the hope that the change of air and scene, the exhilarating and fresh breezes of the ocean, may effect a restoration of health and strength. It is probable that very few medical men have had any prolonged personal experience of life on board ship, hence the observations of one of their own profession who "went to sea" in an official capacity may not be altogether useless. My attention has recently been directed to this subject by the fatal result, in several painful instances, of taking invalids from the comforts and luxury of home, and sending them on a voyage, from which they never returned; and as some fourteen years ago I happened to have some practical acquaintance with a life at sea, I venture to give my reflections on the matter. In discussing this question, I propose to confine my statements to my own individual investigations in those ships and in those climates which I had ample opportunities of studying. The conclusions are based upon the experience of two years, during which time I sailed in many different ships, in every kind of weather, temperature, and climate, and at all times of the year. These voyages extended to different parts of the Mediterranean, of Egypt, India, China, and Japan. During this time I had numerous patients of all classes under my own immediate care, private individuals, public officials, invalids from the services, as well as many others sent out from England by medical men, for the benefit of their health. Every facility was obtained for visiting the hospitals and consulting the practice and opinions of medical men over a considerable portion of the world. In addition, it was part of my duty to study the advantages, and to modify the evils, of a sea life on behalf of the numerous sick under my own immediate care. On these grounds I venture to offer a few remarks on this subject, for the benefit of those who may not have had the fortune, or rather the misfortune, to acquire practical experience for themselves.

Medically considered, we have first to enquire—*Is a life on board ship a healthy one?* It is generally supposed that a sailor, *par excellence*, is the type of good health. The infallibility of this, like that of many other popular dogmas, is questionable. It is true we meet many seamen who are admirable specimens of a robust constitution, as we do in all trades, no matter how unhealthy. It is equally certain that on looking over the crew of a ship, we see only strong vigorous men. But it cannot be argued from this that a life on board ship is *per se* favourable to health. If these sailors were not in all respects sound, active, and able to do hard work, they would not be afloat, and when their articles expired, which they do at short intervals the individual failing in any one of these qualities would be discharged. Here, as in all public services, we see actively employed on duty only those who are in the highest state of physical development, and who

are suffering from no ailment or disease. But we must not forget all those who have been invalided, those who are constantly being weeded out through sickness, those who have given up the sea as a profession from inability to combat with its hardships, and those who have died from disease aggravated or even produced by a nautical career. The advantages to health that a sea life is supposed to possess may be summed up in the fact that the sailor breathes pure air, free from the contaminations of animal and vegetable life, to which may be added the theoretical tonic effect of the oceanic breezes. On the other hand, there are most serious disadvantages. He is compelled to sleep in an ill-ventilated forecastle or cabin, closely packed with a number of other men, where for many hours he inhales a foul and vitiated atmosphere. His food must be more or less faulty, consisting of salted or preserved meat and vegetables. His exercise is limited. He is exposed to sudden changes of temperature and climate, to damp and wet, to boisterous and unpropitious weather, none of which he can avoid or modify on board a ship. All these may injure the constitution, and sow the seeds of disease. It is impossible, in a brief consideration of the question, to enter into all the maladies to which seamen are subject, or to prove by statistics the mortality among those who follow that calling, as compared with men under different conditions. It is sufficient to say that it is doubtful whether a life on board ship is so healthy as is generally supposed; that, further, it requires the strongest and most robust constitutions to withstand its adverse circumstances, and that although there may be not a few who, pursuing this occupation, reach a ripe old age, there are many who succumb to its unfavourable influences.

Is a Life on Board Ship suitable for Invalids?—To us as physicians on shore this is the question which is of the greatest interest and importance, and on this subject it is believed that much misconception prevails both amongst the profession and public. It is imagined that if a man is in any way ill or suffering from chronic disease, if his means permit, he should be sent a voyage for the restoration of his health. I consider this, in the large majority of cases, to be erroneous in theory as it is fatal in practice. It can be readily understood that an individual indisposed from overwork, nervous excitement, functional derangement, or other temporary affection, would be greatly benefited by a trip for a few weeks in a yacht or sailing vessel. All he requires for his recovery is change of air, scene, and society, with absence from occupation and care. Or a patient having become convalescent from a fever or acute disease, might doubtless by such means be invigorated or even entirely reinstated in his former health. But that any one suffering from chronic disease, or from more than temporary or functional complaints, should make a ship his home for hygienic reasons, appears as a rule to be most unsatisfactory, and generally proves most injurious to the condition and well being of the patient.

The position will be best understood by an example. Let one of those cases specially supposed to derive benefit from a sea voyage be taken, namely one of incipient phthisis pulmonalis. Let every possible advantage be given him, and assume that he is on board a first class ship, supplied with every convenience and comfort, that he has an experienced surgeon to attend him, and wealth to procure every desirable luxury. What is his position? His field of action is limited to a ship. He has at his disposal, or probably shares with one or more other passengers, a cabin about eight feet by six in size, where he sleeps and dresses, and which constitutes his sanctum. This is always so constructed that it is open on all sides in order to have free ventilation, and that the inmates may have as much fresh air as possible. During the voyage the patient is at all times liable to exposure of every kind, to sudden change of temperature and climate, extremes of heat and cold, damp and wet, wind and boisterous weather, sea sickness, improper quality of food and drink, deficient exercise, &c., without any means of regulating or diminishing the discomfort and misery attendant on all or any of these evils. In cold weather our consumptive has no means of keeping himself warm, and accordingly he is compelled to shut himself up in his cabin. Here he is either subjected to violent draughts, or, if he partly obviate these, he is obliged to breathe a close and contaminated atmosphere. If to avoid this he attempts, well clothed, to go on deck, he suddenly emerges into cold, bleak, damp winds, which will under no circumstances improve the condition of his cough or lungs. In hot weather he is exposed to the opposite extreme, and has no means of keeping himself cool, and if his vessel be a steamer, the constant heat thrown out all over the ship by the enormous furnaces do not serve to enhance his comfort. This high temperature causes him to perspire freely, to become weak and languid, and to lose his appetite, all of which are of course very injurious to a phthisical patient. In temperate weather he is certainly more comfortable; but equable and agreeable weather for long together is not very common at sea, there being usually a tendency to wind, rain, and other phenomena, which, however bearable by a healthy man, prove very deleterious to the sick or diseased. The patient under these conditions will find it very difficult to avoid damp and wet. On deck this may arise from the constant exhalations from the ocean, from rain, spray, or a sea washing over the deck. If in order to escape these he retires to his cabin, even in the best ships this will probably leak to a certain extent, and if made taut, it will be close, damp, and disagreeable. In rough weather, for the same reason, he cannot remain "above." "Below" he is miserable. While the ship is "knocking about," he cannot walk or otherwise exercise himself; he is probably sick or nauseated, which prevents him taking nourishment for days or even weeks together, and the rolling of the vessel causes him to lose his sleep. It is not necessary to particularise more fully all the petty discomforts on shipboard, such as the shouting and noises at unseasonable hours—if in a steamer the constant vibration of the engines, and the horrors of coaling at every port—the working of cargo, washing the decks at 4 a.m. every morning, restless nights due to crying children, occasional storms, and a host of other annoyances and troubles. These often cause an ordinary passenger to realise that the poetical idea of "a life on the ocean wave," has perhaps been somewhat overrated.

Under these circumstances the surgeon is called in. Let us assume him to be skilful and attentive. The means of relief at his command are, however, both limited in quantity and defective in kind. On an emergency, general attendance in the shape of an experienced nurse is wanting. The food must of necessity be more abundant than delicate in quality, and all the little luxuries, and even necessaries, which an invalid requires, such as milk, fresh eggs, &c., are always difficult or even impossible to procure. Added to all these discomforts, there is a monotony about a life at sea, a want of employment both for mind and body, which must be greatly to the disadvantage of any patient. He has little or no resources, and of those few at his command he soon wearies. He feels unsettled and uncomfortable, he longs for home faces and comforts, and thus *ennui* becomes a serious addition to his already existing malady.

These unfavourable conditions are not peculiar to any vessel or class of vessels, but are inherent and unavoidable in a life at sea, of whatever size, kind, or quality the ship may be. If those enumerated above

are a few of the drawbacks attendant upon vessels of the highest class, the position is not improved in those of a second or third-rate order. What it is desired most particularly to point out is, that while all these annoyances and deficiences may be bearable or even acceptable to the healthy, they are fatal to the comfort, happiness, and recovery of the sick or diseased.

It may be said that, in discussing this subject, the part of a special pleader has been taken, and that the evils attendant upon a sea voyage have been exaggerated. I have no special object in supporting one side of the question more than the other, beyond the interest common to all medical men, of attempting to determine what is best for the patient. I only endeavour to record without prejudice, what was ascertained by my own personal observation and experience. Having had to treat many cases of pulmonary, cardiac, hepatic, and other diseases on board ship, and consequently having had ample opportunities of appreciating the difficulties attendant thereon, I have come to the conclusion that patients requiring the usual accompaniments and necessaries of the sick room, are entirely out of place at sea, and that those suffering from any serious or organic disease are likely to receive more harm than good in submitting themselves to a ship's discomforts. It will be urged, that many persons have greatly profited, and have even completely recovered, by taking a long sea voyage. It is granted that under certain circumstances, in special climates and temperatures, at selected seasons of the year, some patients may have been benefited, but it is maintained that this is the exception, as prolonged favourable surroundings are unusual on board ship. On the other hand I have repeatedly seen persons whose symptoms became worse the moment they were exposed to a sea life, and whose premature death on board was, I believe, in great part owing to the peculiar circumstances in which they were placed.

It may be further said that no physician would think of recommending a sea voyage to any patient who was seriously ill. I can only say that when aboard, scarcely a month passed that I was not called upon to attend two or three individuals suffering from organic disease, who had been sent from England by their medical attendants for the benefit of their health. Moreover, in discussing this question with various members of the profession, the opinion seems to be very prevalent that, in many cases of this nature, a sea voyage is to be highly recommended. They are quite conversant with all its supposed advantages, but they entirely ignore its discomforts and deficiences. To sum up, I believe that persons suffering from overwork, temporary ailments, and functional diseases, as well as convalescents, may derive benefit from a short trip to sea, in a good climate, and at a seasonable time of the year. But I am strongly of opinion that invalids, properly so called, afflicted with organic disease, are in the great majority of cases rather injured than improved by a life on board ship, and that the physician should be very careful in recommending his patient to encounter the hardships of the sea.

CURIOUS CASES OF ANEURISM.

By W. ALEXANDER, M.D., F.R.C.S.,
Surgeon to the Liverpool Workhouse Hospital.

Surgical aneurisms, that are indicated by expansile pulsation, or that manifestly collapse and refill as the blood-stream is shut off or allowed to flow, are so well known, and so common, as to cease to be interesting.

Medical aneurisms are just as common and, when the pressure effects are distinct, are just as easily diagnosed and as uninteresting as are surgical aneurisms.

I do not, therefore, intend to refer to the ordinary cases of aneurism in this paper, a great many of which I have examined both before and after death, but only to those cases in which the disease produced curious symptoms during life, or presented pathological curiosities after death. Nor even in these cases do I intend to refer to all the ordinary symptoms observed, or to give daily notes of the progress of the lesion; my object is rather to sketch the ordinary outlines, so that they may be easily filled in by the experienced reader; and to render prominent the interesting points so as to prevent them being lost sight of in the midst of dry details that very few have the courage, the patience, or the time, to read through.

Case 1.—*Aneurism in Hunter's canal occurring in a lunatic—Ligature of femoral—Sac opened surreptitiously by the patient—Pyæmia and death—Post mortem.*

James R., æt. 48, was playing with a chisel and hammer when he was fourteen years of age. He accidently cut himself on the left thigh above the knee, and from the cut there resulted a traumatic sacculated aneurism of the left femoral artery in Hunter's canal. The aneurism does not seem to have given the patient much trouble until lately, either by its size or by its effects. He has been for several years a lunatic, an inmate of the Lancaster Asylum, and a pauper, belonging to the parish of Liverpool. In the beginning of 1881, the aneurism began to enlarge rapidly, and in March its appearance was so serious that he was transferred to the Liverpool Workhouse Hospital for operation. On March 26th I tied the superficial femoral at the usual place. The pulsation immediately ceased, and the operation wound healed as quickly as a wound could heal that is constantly disturbed by its owner, who wishes frequently to see how it is getting on. The aneurism was gradually subsiding, although not so rapidly as the patient desired, if we may judge from his frequent importunity "to have it opened and the matter inside let out." The terrible consequences of such a procedure were again and again impressed upon him, and the leg was wrapped in cottonwool to keep the tumour out of sight. He was carefully watched both by day and by night.

In the second week in July, he had become, apparently, more contented and acquiesced in the belief that time would make him all right.

On July 14th, he was grinning with pleasure as we approached the bedside, and called out, "Now I will soon get well, the lump is open at last." When the leg was exposed, a small ragged hole was found on the summit of the aneurismal swelling, whence some red grumous material was exuding. On accusing the patient of tampering with the wound, he readily admitted that he had done so, and showed an old nail that he had picked up, polished and sharpened for the purpose, when he was unobserved. The whole mass of blood-clot in the aneurism rapidly became putrid, and the patient died on August 19th from pyæmia and hæmorrhage. Free incisions and antiseptics relieved him for a time, but the evacuation of one putrid cyst was soon followed by the formation of another in the softened infiltrated tissues of the enormous calf of the man who was about 18-stone weight. When death at last threatened, amputation was out of the question, and even when the puncture was discovered it is questionable if amputation at the hip would have been justifiable on a patient so oppressed with "blubber," although, as the case turned out, it would probably have afforded him the "best chance."

On *post-mortem* examination the common femoral was a fibrous cord. The aneurism was irregular in shape, without any defined wall, and contained much débris, and suppuration material. The liver was loaded with fat, and was broken down by pyæmic foci at numerous spots.

Case 2.—Cerebral softening and paraplegia—Undiagnosed aneurism the cause of both.

Henry S. F., æt. 45, a collector of parish rates, became sick in the beginning of 1878. Dr. Shearer, who then attended him, described him at that time as suffering from symptoms of softening of the brain, such as partial loss of power over the limbs, with normal sensation, a feeling of numbness, loss of memory, apathetic manner, inability to read, incontinence of urine, and outbursts of passion. There were no symptoms of chest disease.

On May 28th, 1878, a consultation was held on the case between the ordinary medical attendant and a distinguished physician. The patient had now become partly imbecile. He sat tearing paper into bits, scattering these about the room, and sometimes he would destroy valuable things. He was violent at times, and his wife was now recommended to have him sent to a lunatic asylum. The cause was then supposed to be worry, arising from unsatisfactory family affairs.

I saw him officially soon after this, and agreeing with the diagnosis of his previous attendants, I recommended him to be invalided. During the next six months he remained in a very pitiable condition; restless, discontented and objectless, feeble in his legs, his dribbling urine rendering him odorous wherever he went. His mind soon after this began gradually to clear, and he was able to resume some botanical work of which he was very fond. His limbs got a little stronger, and his urine troubled him a little less. He so far improved as to be able to talk rationally, and it began to be whispered amongst his acquaintances and fellow rate-collectors that F. was all right, and that he had been malingering all the time.

On several occasions I had examined his chest for aneurism, but could find no evidence of anything being the matter with his vascular system.

On March 18th, 1881, his son came to say that he had been found dead in the street, with blood pouring from his nostrils. This information at once supplied the key to unlock the whole case. I obtained liberty to make a small opening into the chest, and found an aneurism in the lower part of the thorax that had eroded the bodies of tenth and of the adjacent dorsal vertebræ to such an extent as to open the spinal canal on the right side. The aneurism covered the bodies of the vertebræ on both sides.

It is possible there may have been two diseases here, viz., an unhinged mind from mental troubles, and partial paraplegia with urinary incontinence from aneurismal pressure. It seems to me more probable, however, that the discomfort of the aneurism in its early stage, and the pressure on the sympathetic nerves, produced the cerebral symptoms, and that these disappeared when irritation of these nerves had been followed by their destruction.

The position of the aneurism between the liver and the heart rendered its diagnosis almost, if not quite, impossible, especially as its position was unmarked, either by a murmur or by pain. Any increase of dulness there could not be separated from the cardiac or hepatic dull areas, whilst the diagnostic value of the paraplegia and urinary incontinence was depreciated by the cerebral symptoms that led us to ascribe them to degeneration of brain tissue.

Case 3.—Aneurism of common femoral—Ligature of external iliac—Cure—Subsequent death and post mortem.

David H., æt. 29, admitted on October 8th, 1880. He does not remember any infantile complaints, and never had any serious illness until *three weeks ago*, when his left leg began to swell. He continued to work up to *three* days before admission. When admitted, he was suffering from erythema and œdema of the left leg as far as the knee, and complained of a stabbing pain from the knee to the ankle whenever he put his foot to the ground. On looking higher for the cause of the disease, an aneurismal tumour was found on the line of the common femoral artery, measuring 11½ inches in circumference at the base, and 2½ inches in vertical height. Surprise was expressed at the rapid growth, and at the unconsciousness of the patient of the presence of this tumour, but he persisted in his assertions that both facts were true.

On October 15th, the external iliac artery was tied, under antiseptic precautions, by means of carbolised catgut ligatures. The wound healed readily, the aneurismal tumour subsided gradually, and, with the exception of a threatening of gangrene of the toes that appeared on November 20th and immediately passed away, the after-treatment of the case was uneventful.

He was discharged at the end of the year, with a small nodule, the size of a marble, at the seat of the aneurism. This nodule was firm and painless, and did not pulsate.

I did not see the case again until November 8th, 1881, about thirteen months after operation. He was then on the *post-mortem* table, having died from an aneurism of the aortic arch that opened into a bronchus and produced death from pulmonary hæmorrhage, whilst under the care of my colleague.

The aneurism of the common femoral was collapsed to a small flattened sac, half an inch in its greatest diameter. It contained a small inner fibrous mass or sac, which occluded the openings of the numerous branches of the common femoral that issued from the aneurism. These branches contained fluid blood quite up to their origin, this fluid blood beating, as it were, against the outer surface of the intra-aneurismal sac. The artery leading to the aneurism was occluded at the seat of ligature by being converted into a fibrous cord. The artery between the ligature and the aneurism was merely collapsed, its thread-thick lumen being filled by a faint cord of fibrine unattached to the interior of the collapsed vessel.

Case 4.—Pulsating tumour of orbit—Ligature of common carotid—Relief and cessation of pulsation—Epilepsy—Death subsequently—Post mortem.

Catherine Murphy, æt. 24, was admitted to the medical wards of the Liverpool Workhouse on April 27th, 1882. She came under my care on May 23rd, 1882. The sight of the left eye became impaired after scarlet fever, two years ago. Five months since, the sight of that eye was completely lost. She has noticed the pulsation and protrusion of the eye for some time.

On admission, there was considerable proptosis, complete blindness, and fixed pupil. The pulsation above the eye and beneath the upper lid was very distinct, and on deep pressure some hard irregular bodies were felt deep down in the orbit. Pressure on the common carotid produced complete cessation of the pulsation, which lasted as long as the pressure was kept up. The sight of the other eye was good.

On May 24th, the common carotid artery was tied at the usual place, under antiseptic precautions, with ordinary catgut ligatures. When she awakened from the anæsthetic (chloroform), she declared she could see better already, and was able to discern the white ceiling; the pulsation had completely ceased, the eye had receded, and between the roof of the orbit and the eyeball there could be felt hard irregular masses, assumed to be coagula, but without sufficient reason. The operation wound healed without any trouble.

On June 7th, the patient thought the eyesight of the left eye was getting a very little clearer. She could see a little better on clear bright days than on dark dull ones. On June 15th, she had an epileptic attack, succeeded

by seventeen others during the next eight hours. The face was most affected by the convulsions, but the whole body participated in the movements. The patient was unconscious on the 16th, and did not recover until after profuse movement of the bowels, the result of a large enema. Her temperature before the enema was 103°.

June 27th. The patient became very noisy and excited to-day, and on two occasions attempted to strangle herself with a bandage. On July 4th, the same kind of excitement was observed, followed by another attempt at strangulation. On July 23rd and 27th, and August 3rd, she passed through similar excitable moods to those described, without, however, attempting suicide. She was sent to the infirm wards on November 3rd, on account of want of room, where she stayed till June 12th, 1883, the date of her death. Complete blindness of both eyes took place during that time, the epileptic seizures occasionally occurred, and the epileptic mania more frequently. Helplessness and inability to attend to nature's wants preceded the comatose state in which she died. The pulsation never returned in the left eye.

The *post mortem* was made on June 14th. The calvarium was beautifully thinned all over through intra-cranial pressure. The bone just below the frontal eminences was completely absorbed. The left supra-orbital arches had also disappeared, and the roofs of both orbits were absent, so that the orbit and its contents were plainly visible when the brain was removed. The cribriform plate was absorbed, and the nasal cavities exposed from above. The left optic nerve was stretched to about twice its length between the optic foramen and the entrance into the globe of the eye. It was, to a corresponding extent, thinner than usual. The right nerve was slightly stretched and thinned, and there was some proptosis of that eye.

The contents of the orbit were otherwise normal, the diseased mass being entirely outside these cavities.

The anterior lobe of the left side of the brain was entirely occupied by a large greyish vascular tumour, that made that lobe seem twice its normal size. At the inner side an offshoot of the growth occupied the anterior part of the longitudinal fissure pressing behind on the genu of the corpus callosum, and to the right, burrowing beneath and producing absorption of the right anterior lobe. The disease had infiltrated the anterior part of the left corpus striatum, and of the corpus callosum.

The common carotid was occluded up to the ligature. The internal carotid was pervious. The other organs of the body were healthy.

A NOTE UPON TREATMENT OF FRACTURES IN THE VICINITY OF JOINTS BY PLASTER OF PARIS BANDAGE.

By A. MARMADUKE SHEILD, M.B. Cantab., F.R.C.S. Eng.,

Late House Surgeon to St. George's and Addenbrooke's Hospitals.

Attention has lately been called to the utility of the practice of the immediate employment of the plaster of Paris bandage in ordinary fractures of the limbs. The appropriate cases were so fully described, the methods of application so well illustrated, by the eminent authorities who brought the subject forward, that it would seem that little remains to be said on such an important branch of treatment. My object is simply to lay stress upon the value of this method when applied to fractures in the vicinity of joints, which, as every practical surgeon knows, are often dubious in their diagnosis, tedious and difficult in treatment, and, perhaps, unsatisfactory in result. I will confine my remarks chiefly to fractures in the neighbourhood of the shoulder and ankle, which will serve for purpose of illustration, and being injuries commonly met with, are important to treat easily and well.

The student, or practitioner, must be struck, on reference to the ordinary text-books, to see the number of contrivances that are suggested for the treatment, let us say, of the common extra-capsular fracture of the humerus. All the methods aim at the grand principles of adaptation of fragments, and complete rest, yet how prone they all are to fail in carrying these out to perfection is proved by daily experience, and the very number of the methods suggested, as well as their different nature. Turning to the familiar Potts' fracture in the lower extremity, it must be granted that in really bad cases it is extremely difficult to maintain quietude and good position by means of splints. An anæsthetic is given, or, by manipulation, the fragments are restored to their proper position, but in keeping them in that position there is often the greatest difficulty. The pressure exercised by the bandages and splints upon the œdematous parts becomes risky, the position is irksome to the patient, the pain is unendurable, movements on the part of the sufferer ensue, and when the surgeon views his carefully adjusted fracture, the sharp broken edge of the inner malleolus will still, to his dismay, be seen projecting against the skin and threatening further damage.

Indeed, a very great deal depends upon the conduct of the patient; with an unruly, irritable, or delirious individual, the difficulties of the splint treatment become vastly increased. How often have we heard the surgeon say in such cases, "if he throws himself about in that way, the fracture will soon become compound!"

All the difficulties arise from one great cause, the impossibility of securing a good hold upon both parts of the fractured bones. Splints can not well be applied from the contour of the parts; a nearer approach to the right method is in the gutta-percha or leather case, and did this accurately fit, perfectly hold the limb, and remain quite immovable, everything would go smoothly.

In considering the fitting of plaster of Paris bandage to a fracture near a joint, we must first attempt to lay down some rule for the time of its employment. If there be no great swelling, or contusion of the soft parts, it may be used at once, but in the majority of cases, I think it better to wait for about a week, until the extravasated blood shall show signs of absorption, and the inflammatory swelling begin to subside. During this short time the part can be supported in some suitable temporary apparatus, and evaporating lotions applied.

On the subsidence of the swelling a more certain diagnosis, and accurate idea of the relation of the fragments, can be obtained. When the surgeon has determined to adopt the more permanent apparatus, he collects his materials; these are simple.

The skin must be protected by a flannel bandage, which is applied evenly and smoothly over the whole part. Should the skin be abraded, a simple ointment may be spread beneath the bandage, cottonwool may be used over any part or projecting fragment.

Half-a-dozen bandages rolled in dry plaster are now prepared. The material is most important, it should be the coarsest muslin, so that the plaster and moisture may easily permeate the whole mass when adjusted.

The bandages should not be more than two inches in width; a narrow bandage can be made to fit and insinuate itself into the inequalities of a part in a superior manner to a wide one. Some loose dry plaster in a basin, and plenty of warm water, are all the other things needful.

The surgeon having applied the protecting flannel, proceeds to the "setting" of the fracture. In doing this he should use the greatest care and gentleness, and grudge no time or caution. It is often well to employ an anæsthetic; a more certain opinion can then be formed of the injury, while the released muscles allow the broken bones to move about freely, and they crepitate between the hands of the operator, who may place them in the most accurate position.

Now comes the work of the assistant, and this though simple, is hardly second in importance to that of the principal operator. He has to hold the fracture in *exact position*, during the application of the apparatus. In some cases he may have to make extension as well, but he should ever recollect, that he must not let his attention flag, or his muscles relax from the work he is doing, or else the fracture will tend to again assume its faulty position, and be so fixed by the plaster of Paris. More failures occur from the employment of a careless or untrustworthy assistant than may be generally supposed. One of the bandages, rolled in plaster, having been well soaked in warm water is now to be applied firmly, not tightly, from below upwards. Over this a layer of loose dry plaster is laid, which is then well wetted and rubbed in with the hand. Another bandage is now applied over the first, and upon this dry plaster again sprinkled, well wetted, and moulded with the hand.

Five layers of the muslin usually suffice to give strength and solidity to the apparatus, and the result is not a heavy cumbersome mass, which, difficult to remove, irksome to the patient, has so often brought discredit upon the method and operator, but a light shapely splint which quite fulfils its object, and is a source of the greatest pride and comfort to the patient. It must be remembered that the plaster soon "sets." In fact, after the application of the third layer, the assistant will begin to feel that the fracture is being held in its new position. He must not on that account relax his attention, but, if possible, rectify any slight displacement in the axis of the limb, or of the fracture, that he may notice before it becomes too late. It is also most essential that the plaster be well wetted and moulded together, the splint then forms one harmonious whole, and does not crack or give way. The apparatus may be removed in five to six weeks, and passive motion cautiously commenced.

The advantages I claim for this mode of treatment, when properly carried out, are not a few.

The country surgeon may apply it with the greatest ease, as all the materials can be carried any distance in a small parcel. When once the apparatus is applied no efforts on the part of a delirious or troublesome patient can displace the fracture, therefore it is most useful in the very cases where movable contrivances fail. It is exceedingly comfortable to the patient since it prevents any movement of the broken ends of the bones. Lastly, the result is satisfactory, for as complete rest is maintained, the fracture unites the sooner, and without those masses of callus which so impede the after functions of a joint, and without the chronic inflammatory changes which implicate the tendons and muscles. Consequently, passive motion may be earlier and more successfully carried out, to the credit of the surgeon, and ultimate great benefit to the patient. I am confident that if practitioners would more generally adopt this line of treatment they would feel every reason to be satisfied with it, and would say with me, that it bears favourable comparison with any other.

AMENORRHŒA AND VICARIOUS MENSTRUATION.

By NORMAN CHEVERS, C.I.E., M.D.,
President of the Epidemiological Society.

I HAVE read, with that pleasure which their writings always give me, the recent observations of Drs. Matthews Duncan and Wilks on the above subjects. I agree with Dr. Wilks in considering that their just views on the former condition are quite in accordance with those of the best observers of our time; but, while I, of course, do not believe that the function of menstruation can be transferred from its proper organ to the lung or stomach, or to an ulcer on the leg, I know that women who do not menstruate normally, are liable to discharges of blood or hæmoglobin after modes which do not obtain in the male. I think that, in his student days, Dr. Wilks must have been told by Mr. Callaway, in the out-patient room—"Look, my dear fellow, that is a menstrual ulcer." I do not know by what name these ulcers are now recognised; but, assuredly, they were never seen in men. Their appearance was so characteristic as to distinguish them, at a glance, from all other sores, and their discharge was not pus, but a cruor of a dirty damson colour. I have more than once seen plum-juice expectoration in women who were "irregular," but who had no organic pulmonary or cardiac disease. One of these patients, an East Indian lady, whom I attended more than 30 years ago in such an attack, and in whom there was no sign of heart-obstruction, and no concurrent evidence of tubercular or lung mischief, came to England a few years ago, and is, I believe, still residing in my neighbourhood. The late Dr. Duncan Stewart, Professor of Midwifery in the Calcutta Medical College, published in vol. 3, p. 47, of the *India Journal of Medical Science*, the case of a French woman who had alarming hæmoptysis. This "was found to be connected with menstrual obstruction and enlarged spleen. The discharge continued three days. She brought up two pounds of blood. Two relapses had occurred. For a day or two before the bleeding began, the spleen became enlarged, and felt heavy and painful, causing nausea and faintness when the patient walked." It must here be recollected that, in India, women who have great splenic hypertrophy or confirmed malarious anæmia, are generally amenorrhœal. I do not regard these voidings of disintegrated blood as in any valid degree compensations for the suspended menstrual function. Still I cannot doubt it to be a fact that women in whom this function is inadequately performed are liable to sanguinolent oozings from various surfaces.

THE CHINESE AS PATIENTS.—According to Dr. Brown, of San Francisco, the Chinese must make very good patients, for they invariably carry out instructions to the letter, are very grateful, and always pay their bills. Constipation is almost unheard of amongst them. Their children are usually much smaller at birth than white babies, six pounds being an average weight. They use paper on the lying-in bed as a protection, and thin paper as napkins for the lochia. It has the appearance of a muslin fabric, being thick and soft, and is prepared from a stout paper of a light brown colour, smooth, and bearing no resemblance to that in use. It is prepared by simply crumpling and rubbing it with the hands. Being tough and thick, it is completely transformed by the process and makes a soft fabric, almost impermeable to water, and admirably fitted for temporary protection of the bedding, one sheet being replaced by another as soon as it has become soiled. Lacerations of the cervix are very rare among them.—*New York Med. Record*, January 5th.

Medical Times and Gazette.

SATURDAY, FEBRUARY 23, 1884.

THE subject of over-work in elementary schools still excites, we are glad to see, a considerable amount of attention in Parliament. From a statement made by Mr. Mundella, we learn that it is true that Her Majesty's School Inspector for Southwark has reported that fourteen certificated teachers in his district had broken down from over-work under the new Code; and that two of them had died. The report has been forwarded by the Education Department to the London School Board, and the statements made in it are being strictly investigated. Mr. Mundella has also invited Dr. Crichton Browne to visit some of the "public elementary schools of London," meaning thereby, we suppose, the School Board schools, and to give the Education Department the advantage of his opinion as to their work from a sanitary point of view. Mr. Mundella is instituting, he assures us, the most careful and searching enquiries into the allegations of over-pressure in these schools, and will communicate the results to Parliament. It is to be hoped that the investigation will be most impartial as well as thorough. Up to the present Mr. Mundella has, apparently, been quite unable to conceive that the Code can be in any way at fault.

THERE appears to have been some degree of misunderstanding as to the purposes to which the proposed hospital at Winchmore Hill is to be devoted. The Southgate Local Board strongly object to the proposal of the Managers of the Metropolitan Asylums District to purchase the above-mentioned site for the erection of a convalescent hospital, and have besought the Local Government Board to refuse to sanction the project. The Local Government Board, however, do not agree with the views of the Southgate Local Board, and have assented to the proposals of the Asylum Managers; and according to the statement made by the Parliamentary Secretary of the Board, Mr. G. Russell, in answer to a question put in the House of Commons, it appears that the ground, or the main ground, was that the proposed hospital is to be for convalescent fever patients only, and not, as had been thought, for convalescent fever, and small-pox patients. We think that, as the site concerned comprises more than 36 acres, the Southgate Local Board need not have opposed the erection of the hospital, even had it been intended for the use of small-pox convalescents as well as for convalescents from fever.

SOME of the Irish Members of Parliament display a really marvellous capacity for hunting up mare's-nests, upon which they may found questions in the House of Commons; and not a few relate to suspected or alleged evil-doings of medical men. Two of the questions put on Monday last are typical examples. One Irish M.P. asked whether it was true that three prisoners in Belfast Gaol had died within the past month? how long they had been ill? and why the medical officer did not recommend their release. The reply, by that much enduring official, Mr. Trevelyan, was that one prisoner had died in the prison mentioned within the last month; that he was under treatment for a fortnight before his death; and that his release had not been recommended because the medical officer did not consider that his illness was either due to, or aggravated by, confinement, and did not think that he would in any way benefit by being discharged. Mr. Trevelyan added, as a proof of the healthiness of the gaol, that prior to the death of this man, no death had occurred in the prison since May, 1882.

ANOTHER Irish Member, who ought to have known better, made, or implied, an attack on Dr. George Sigerson, a very well known Dublin physician of high scientific and literary attainments. Mr. Trevelyan was asked whether Dr. Sigerson was the writer of many articles of a seditious nature in the *Irishman* newspaper, and was believed to have acted as sub-editor of that paper during the imprisonment of Mr. Pigott, and whether he had been appointed to a position of trust and influence by the Government. The answer was that Dr. Sigerson denied having written any articles of a seditious nature, and denied having been sub-editor of the *Irishman* during Mr. Pigott's imprisonment, which had occurred seventeen years ago; and Dr. Sigerson further declared that he is not, nor has for a considerable time been, a contributor to any newspaper. He is a member of the Royal Commission to enquire into the administration of prisons in Ireland. That is the only appointment he holds in connection with the Government; and Mr. Trevelyan very rightly observed that Dr. Sigerson's position in the profession, and the special attention that he has given to matters concerning the public, amply justified his appointment by Government to the post he holds.

MR. RICHARD'S Bill, to amend the law relating to cemeteries, has not the slightest sanitary significance. Its object is to relieve burial authorities from the existing obligation to divide burial grounds into consecrated and unconsecrated parts. The Bill does not prohibit the consecration of cemeteries or of chapels, should Bishops think fit to consecrate them; but it would forbid cemetery authorities to apply for the consecration of a cemetery, or of any part of one, or for the consecration of any building within, or in connection with any cemetery; and it would enact that "every cemetery and part thereof, and building therein, shall, whether consecrated before or after the passing of this Act, be as available for burial services otherwise than according to the rites of the Church of England, as though it had not been consecrated." It would appear that so soon as any portion of a burial ground, or any chapel in a burial ground, is consecrated, it thereby acquires a special value in the eyes of those who are not themselves believers in the rite of consecration. It becomes a Naboth's Vineyard to them while living, and they desire to have the right to go in and possess it even when dead. As the great

object of the Bill is to minimise the value of consecration so far as concerns cemetery arrangements, it is satisfactory to find that Clause 13 prohibits the removal of corpses from any part of a cemetery without the consent of a Secretary of State, and the use of a cemetery for any purpose other than that of burial without the authority of Parliament.

At the Medical Society on Monday last, Dr. Sidney Coupland opened a discussion upon the cold-bath treatment of enteric fever. He began by remarking, that treatment might be pursued on three distinct lines: the specific, the expectant, and the anti-pyrexial. As regarded the first, he said the specific poison or germ was not sufficiently understood at present to allow of any definitely specific treatment. The expectant method was that most in vogue; this, of course, included such anti-pyrexial methods as were administered solely with a view of relieving excessive temperature. The treatment of typhoid by cold, upon which Dr. Coupland mainly dwelt, was first systematically advocated by Brand, of Stettin; it differed from the expectant in recognising the direct danger to life of long-continued pyrexia, and had for its object less the mere *reduction* of excessive temperature, *than the maintenance* of a diminished febrile process *throughout* the whole course of the disease.

The three methods most in use in this plan of treatment were, he said, sponging, cold compresses, or ice-bags, and the cold bath. Dr. Coupland gave good reasons for preferring the last named in severe cases, reserving the other and milder methods for cases in which the bath, for some reason or other, could not be had, or was specially contraindicated. After giving a comparative analysis of the fatal cases, as to period and cause of death, he showed that, at the Middlesex Hospital, where anti-pyrexial treatment had been more or less systematically carried out of late years, the gross mortality due to pyrexial causes had been notably diminished. His personal experience, however, was based on 89 consecutive cases, of which seven were fatal, treated in his wards from 1879–1883. Of the fatal cases, one only was directly due to pyrexia. He contrasted these 89 cases with 75 others (admitted during 1873 before any systematic anti-pyrexial treatment was pursued), of which nine were fatal, four of these deaths being due to the effects of high fever. Illustrative cases were related, and special attention was directed to the leading points in each of his fatal cases, the object being to show that death occurred mostly from intestinal lesions, in cases admitted late on in the disease or during relapses; and that the fatal issue could not be attributed to the bathing.

Dr. Coupland believed that if this treatment were commenced early enough, and systematically carried out, it might possibly abort the fever: but failing any control over the intestinal lesions that it undoubtedly allayed the nervous symptoms, practically banished the "typhoid state," lessened the tendency to sequela, and materially hastened convalescence. He particularly urged that this treatment was not generally contraindicated by the asthenia natural to the febrile state, nor by pulmonary complications; and that it did not appear to increase the liability to intestinal hæmorrhage or perforation, which, when found, obviously depended on the extent and severity of the local lesions peculiar to, and characteristic of, enteric fever.

Dr. Bristowe followed with a paper, in which he argued against this method of treatment. He stated that he had abandoned it some years ago, being chiefly influenced thereto by two severe cases of fatal lung collapse, which he attributed directly to the baths; he believed also, after considerable trial, that it had been abandoned by many other practitioners. He contrasted with this mode of treating typhoid patients the antimonial and calomel treatment of pneumonia and other inflammations, which so flourished for a while as the result of the enthusiasm of those who introduced the drugs; then spoke of the administration of alcohol in overwhelming quantities; methods of treatment, he said, which were largely practised for a time, but which were no longer accepted at the present time. So, he believed, it would be with the bath. He admitted a temporary benefit from baths; but, like that resulting from the intravenous injection of saline fluids in cholera, it practically left the disease uninfluenced. He thought there was abundant evidence to prove the connection between the exposure to cold and internal inflammations and congestions, and he related two marked cases in point. It was, moreover, now generally believed that typhoid and allied diseases were due to germs: he asked, did these cold baths render germs less vicious or kill them? He had not brought any statistics in support of his views, as statistics could be made to prove anything that was wanted. The bath treatment was, moreover, difficult and expensive to carry out. Dr. Frederic Taylor then gave a summary of the experience of Guy's Hospital, and spoke in favour of the anti-pyrexial treatment. While admitting that mortality was the test by which any new method of treatment would be judged, he felt it would not be a correct test in the present instance, as only the severest cases were submitted to the cold-bath treatment. He agreed with Dr. Coupland that bathing, to be really effective, should be commenced early on in the disease. Its immediate effect, he said, was to lessen delirium, and to increase the patient's comfort; and if deaths from hæmorrhage were not diminished, they were not increased, while other complications and relapses were distinctly less common when this treatment was employed. The discussion will be resumed next week.

The exact pathology of infantile paralysis was the first subject under discussion on Tuesday last at the meeting of the Pathological Society, Dr. Money contending that the chief cause was a faulty blood supply, and not an inflammation of the grey matter, as is usually held. His argument was, that there were so many obstacles to interfere with the free access of blood to the grey matter that a very slight cause might suffice to prevent this altogether. Dr. Sharkey and Dr. Wilks, on the other hand, thought that the blood

supply of the grey matter was exceptionally good, the latter observing that the nervous system was especially prone to disease, on account of its great functional activity. Dr. Coxwell read the notes of a fatal case of lateral amyotrophic sclerosis, in which he had found extensive disease of the pyramidal tracts and anterior cornua, the disease apparently having commenced in the latter structures.

As is unfortunately only too often the case, the best paper of the evening was kept till so late that there was not time to give it a fair hearing, much less obtain any discussion upon it. Mr. Watson Cheyne's communication on the presence of micro-organisms in the blood in two cases of purpura hæmorrhagica deserved a better fate than this, but the fact remains that it was hurried over, owing to the lateness of the hour at which it came on. Surely, it must be within the province of the Council to determine the order in which communications shall be taken, and, for our part, we should be glad to see them exercise their discretion in this matter, and also in the matter of relegating communications to the list of card specimens a little more freely.

At the Society of Medical Officers of Health on Friday last, Mr. Cassal read a paper embodying certain observations and experiments by himself and Dr. Whitelegge on the albuminoid ammonia and Frankland's methods of estimating the purity of potable waters. They found the former to give results so uniform, when applied to waters of known degrees of pollution, that they pronounced it sufficiently accurate for all practical purposes, and on the score of speedy performance and simplicity much to be preferred to Frankland's. In a discussion of unusual interest, the feeling of medical officers of most experience was, that the value of the conclusions to be drawn from the most complete analysis had been greatly exaggerated, while many published analyses conveyed no real information whatever, since chemistry totally fails to indicate the nature of the organic matter, and whether living and specific, or not, and that the analysis should rather be deemed subsidiary to, and confirmative of, microscopical, physiological, and other evidence.

At the annual meeting of the Obstetrical Society of London, Dr. Aveling mentioned that the Society had some time since asked Dr. Fordyce Barker, of New York, to have made for them a transcript of Woolveridge's "Speculum Matricis." This book, published in Dublin, 1670, is the earliest original work on midwifery in the English language, and the only copy known to exist was in the possession of Dr. Fordyce Barker, who, at the request of the Society, employed a man to copy it. This person absconded with the volume, and died in Europe. Thus, it is feared, the only copy of this work has been irretrievably lost. It is asked that if any of our readers should meet with or hear of a copy of this rare book, they will inform the honorary Librarian of the Obstetrical Society of London.

At a general meeting of the Fellows of the Royal College of Surgeons in Ireland, held on Friday, February 15th, Dr. W. Ireland Wheeler, president, in the chair, the following resolutions were, after prolonged discussion, carried by large majorities:—1. Resolved—"That this meeting approves and will gladly support a well-considered measure of reform calculated to remove such defects as have been proved to exist in the constitution of the medical profession; but, at the same time, the Fellows here assembled desire to express their conviction that it would be injurious to the public welfare, and an unjustifiable employment of State authority to strip of their priviliges institutions which can be shown to be using them both wisely and well." 2. Resolved—"That, inasmuch as the Bill introduced into Parliament last Session would, had it become law, have deprived this and other medical authorities of the power and influence over the profession which they have hitherto exercised, and which were conferred on them by charter, the Fellows of this College are of opinion that any such legislation should be resisted by the entire profession as being in a high degree injurious to its best interests." 3. Resolved—"That this meeting having been informed that it is the intention of the Government to introduce into Parliament during this Session a Bill similar to that of last year, recommends the Council to use all the influence it can command to obtain such changes in that Bill as may be necessary to preserve the chartered privileges of the College, more especially the right of conferring a title to practise, and, failing this, to oppose the passing of such a measure by all constitutional means."

A very full and varied provisional programme of the subjects proposed for discussion in the section of diseases of children at the International Medical Congress, to be held at Copenhagen, in August next, has been issued. The President of the section is Professor H. Hirschsprung, and the Secretary Dr. Wichman. The following are the questions which have been selected:—1. On the use of sea-side hospitals for children. 2. The normal increase of weight in the later years of childhood. 3. The prophylactic treatment of ophthalmia neonatorum. 4. On the choice of antiseptics for the treatment of wounds in children. 5. On the value of the out-patient department for the propagation of sound hygiene among the poor. 6. Nephritis in children, especially in infancy. 7. Tubercular meningitis in the first years of life. 8. Have the experiences of later years been able to fix the systematic place of acute rickets. 9. On intestinal invagination in children, and its comparative frequency in different countries. 10. On the treatment of acute rheumatism in children with salicylic acid. 11. How far is croup to be considered from a clinical point of view—a well limited morbid entity.

The French Society of Ophthalmologists held their annual conclave during the last four days of January. The treatment of granular conjunctivitis by jequirity gave rise to a very good debate on the first day. Amongst other subjects dealt with during the Congress we note the treatment of detached retina, the treatment of ophthalmia neonatorum, the diagnosis of hemeralopia, the ocular manifestations of scrofula and

hereditary syphilis, and the connection between eye affections and disorders of menstruation. The announcement, on the opening day, that Professors Donders and Arlt had joined the Society was received with evident satisfaction.

At a meeting of the Royal College of Physicians, on Thursday last, the President announced that, in conjunction with the President of the Royal College of Surgeons, he had had a long interview with the Home Secretary to urge upon him the desirability of providing in some way that the Public Prosecutor shall seek good medical advice before he decides to undertake the prosecution of a medical man for a criminal offence on a professional matter. The Home Secretary discussed the matter very fully, and we have good reason to believe that the ultimate result will be highly satisfactory.

Sir Risdon Bennett will represent the College of Physicians at the forthcoming tercentenary celebration of the University of Edinburgh.

The Liverpool poisoning case which has been dragging on for weeks in one court or another, ended on Saturday last in the conviction and sentence to death of both the prisoners. The case was a sordid and hateful one from beginning to end, and the public evinced little interest in it. And yet it is important as showing once again how slow people, and even doctors, are to suspect foul play, especially when the victim is of the flesh and blood of the murderer. Another lesson which the case once again brings into prominence is the temptation to which the system of burial clubs exposes covetous and unscrupulous persons. It will be long, we imagine, before the poor can be induced to lessen the ceremoniousness of the one event which breaks the monotony of their lives—a funeral. But until they cease to think it right to spend the savings of years in one day on mutes and mourning coaches, it might be as well to make it incumbent on the burial clubs to pay the undertaker, and all other funeral charges, direct. That would at least do something to prevent a life being insured, as in the Liverpool case, in five burial clubs at once.

The Apothecaries' Society have issued a circular to the effect that chemical and microscopical analyses are now performed in their laboratory at Blackfriars, under the direction of the superintendent, Mr. Robert H. Davies, F.I.C., F.C.S., who will undertake the examination of water for drinking purposes, of articles of food, as to their freedom from adulteration or poison, and the assay of drugs and chemicals.

Contrary to the ordinary usage of medical societies, the Berliner Medicinische Gesellschaft has lately devoted the whole of two of its meetings to the discussion of a purely political question. The action of the Baden Government in establishing a form of State control over the medical profession within the duchy, to which we referred a few weeks ago, has been received with but little favour by the medical profession in the capital of the German empire. Although, presumably, it can only be held to represent the views of its own members, the Medicinische Gesellschaft has proclaimed in unmistakable terms the opinion at which it has arrived, after a long and by no means one-sided discussion. It considers "that State supervision over the profession is neither consonant with the wishes of its members, nor with the general interests of the public." At the instance of Professor Virchow, who occupies the chair during the present session, a slight addition to this somewhat curt resolution was adopted, expressive of the satisfaction that would be given by some State recognition of medical representation.

In the course of a recent discussion in the Prussian House of Representatives on the nursing sisterhoods, Prof. Virchow paid a compliment to England which ought not to pass unnoticed. "As a matter of fact," he said, "a satisfactory organisation for the care of the sick has only been as yet devised in one country, where it has been taken up with such a strong bent as to carry it far beyond anything that Catholic sick nursing has so far attained to, where, in fact, the devotion even of the upper classes has been such that nothing that the Catholic Church has provided can be in any way compared to it—(laughter from the Catholic party). Gentlemen, can you point to a place in which the Catholic Church has done what is done in London, where a succession of members of the aristocracy go as nurses into the houses of the sick poor? I have always held that this is a matter in which we may all leave our religion at home, and work together simply as fellow-men."

Early in January an interesting ceremony took place, at the castle of Nymphenburg, in the presentation to Prince Ludwig Ferdinand of Bavaria, so well known for his scientific acquisitions, of the diploma of Doctor of Medicine, *honoris causa*, of the medical faculty of the Bavarian University. On his presenting to the faculty a copy of his recently completed work on the comparative anatomy of the tongue, "Zur Anatomie der Zunge," it was unanimously determined to confer this degree on its author, and a deputation was chosen in order to present the diploma to the Prince. The deputation consisted of Professors Pettenkofer, Rüdinger, and Kupffer. In his address, Professor Pettenkofer dwelt upon the satisfaction with which the medical faculty had witnessed the Prince's devotion to science, and the signification they attached to this honorary degree, which is the highest mark of distinction the faculty has in its power to grant. The Prince, in reply, warmly thanked the deputation, assuring them that he felt proud of being thus distinguished by a faculty which numbered amongst its members some of the first *savants* of Europe. For himself, he felt an unbounded love for science, and he hoped to show by future work that he was worthy of the honour conferred upon him. His treatise consists of fourteen sheets of text, with 104 chromo-lithographs, and is dedicated to King Ludwig of Bavaria. The investigations were conducted under the superintendence of Professor Rüdinger.

**

The substance of Dr. Koch's fifth report, dated Calcutta, January 7th, to which we alluded last week, is to the following effect. After expressing his thanks for the way in which the Commission had been received by the medical authorities at Calcutta, Dr. Koch states that he and his associates have had an opportunity of making *post-mortem* examinations of nine cholera subjects, in all of whom they found the same bacilli as they discovered at Alexandria. They isolated them, cultivated them in gelatine, and observed in them certain characteristic features which enable them to differentiate them with certainty from similar forms of bacillus. Dr. Koch has also been able to identify the specific bacillus in the evacuations of living cholera patients. His next step was to examine the intestines of patients who had died from other diseases, as pneumonia, dysentry, phthisis, and Bright's disease, for the same bacillus, and in each case without success. He also examined the dead bodies of animals and other substances swarming with bacteria, but in none was the specific bacillus to be found.

Dr. Koch intends to continue these investigations, and if he still finds the bacilli uniformly present in cholera cases, and uniformly absent in all others, he thinks that he will be justified in regarding them as the cause of the disease, even if his inoculation experiments in animals should fail; his results in this direction, however, have been such as to permit him to hope for better success than he has as yet been able to record. Since the last report was published, a statement has appeared in a Calcutta paper to the effect that the members of the Commission have discovered the bacilli in the matter contained in a water-tank supplying a village in the suburbs of Calcutta, in which sixteen cases of cholera had recently broken out. Confirmatory details of this statement will be looked for with some interest.

Whilst the theory of the communicability of phthisis is engaging the attention of collective investigators and scientific observers at home, it would appear that in Germany a more practical view of the question is being taken. The Minister of the Interior, in view of the prevalence of phthisis in prisons, has not waited for the final solution of the problem, but having determined, in true judicial spirit, to give his prisoners the benefit of the doubt, has ordered the isolation of phthisical cases, the careful disinfection of linen and excreta, and all the usual sanitary precautions, such as are observed in the case of the well-recognised infectious diseases in all the prisons and kindred institutions in Germany.

A conscription of idiots and cretins is about to take place in Hungary, under Government supervision, with the object of ascertaining more exactly what proportion the number of cases bears to the population of the country, and also to the number of asylums, or other institutions, provided for their care. The opportunity will not be lost for making further investigations into the true nature of the complex condition known as cretinism, and it may be confidently anticipated that the curious connection between disease or removal of the thyroid gland, myxœdema, and sporadic cretinism, which has of late been clearly recognised, will be still further illustrated and explained, when a larger amount of material, and especially of cases of endemic cretinism, are available for study.

During last week the meteorological conditions, except perhaps on the last two days, were exceptionally favourable to health. The mean temperature was nearly 4° above the twenty years' average for the corresponding week, the night temperature never fell below freezing point, we received 25 per cent. of possible sunshiny hours, and the recorded amount of ozone considerably exceeded the average. Under these circumstances the death-rate in the 28 great towns fell from 20·6 per 1,000 to 20·1, and only twelve of the towns had a death-rate above 20·0 per 1,000, instead of seventeen of them, as was the case last week. In London, however, the death-rate rose to 19·8, having been 19·5 in the previous week. This rise is almost entirely accounted for by an increase in the number of deaths from the zymotic diseases, which were 208 in number, or 34 below the ten years' average, whereas in the previous week they were only 186, or as many as 63 below the average. The zymotic death-rate was 2·7 per 1,000, higher, that is, than it has been in any week since the present year began. Whooping-cough, measles, and diphtheria were the most fatal of the zymotic diseases; whooping-cough being credited with 83 deaths, or exactly as many as those from measles (35), scarlet fever (22), and diphtheria (26) combined.

Small-pox has for some time been very prevalent at Sunderland, and the current return appears to show that it is increasing in severity, ten deaths from this cause having been registered last week.

The watchful supervision of the Local Government Board over the health of the country, sometimes introduces us to places but little known before. Thus, Dr. Parsons was recently deputed to report on the sanitary condition of the Heage Urban Sanitary District, which we find to be in Derbyshire, in the neighbourhood of Belper. The death-rate in this district during the past five years had been, on the average, 19·3 per 1,000 per annum, or considerably above that of healthy rural districts possessing similar conditions, and this, notwithstanding that the total area gave nearly an acre to each inhabitant. Although the sewerage arrangements, water supply, &c., were found to be more or less faulty, the number of deaths from diseases of the zymotic class had been by no means large; and as a result of his investigations, Dr. Parsons reports that, while the circumstances of the district, physical and social, do not call for large and comprehensive schemes, they, nevertheless, demand careful supervision, and the enforcement of improvements based upon the requirements of each individual house.

The first lunatic asylum report that has dawned on us this year comes appropriately from the East—the

East Riding Asylum, which appears to be in a thriving condition under the management of Dr. Macleod. The asylum contained 274 patients on the 31st of December last—66 having been admitted during the previous twelve months, and 75 having died or been discharged. Hereditary tendency to insanity was clearly made out in 21 of the cases admitted, while intemperance was proved to be the cause of the mental malady in seven cases. One man who was admitted, an Irishman, went mad after receiving a letter from a secret society threatening his life; and in two cases insanity was induced by the highly emotional services of the Salvation Army.

An influential committee has been formed, with Dr. Fordyce Barker as its chairman, for the purpose of raising a fund for the erection of a monument in the New York Central Park to the late Dr. Marion Sims. "It is believed," the committee observe in their address, "that the medical profession everywhere, the vast number of women who owe their relief from suffering directly to him, and those who realise the benefits he first made possible, will gladly unite thus to honour the man through whose original and inventive genius such blessings have been conferred upon humanity. The active co-operation of the medical profession and the many other friends of Dr. Sims throughout the world is respectfully solicited. Contributions of one dollar and upwards may be forwarded to the journal which has been constituted the treasury of this fund—*The New York Medical Record*." Substantial proofs of the favour with which this appeal has been received have already been given in the shape of considerable subscriptions, varying in amount from one to 100 dollars.

The interest in medico-legal questions shows every sign of vitality in the United States. It has received a vast stimulus from the results of recent litigation in connection with a disputed insurance case. Notwithstanding the testimony of numerous high authorities, the evidence given by the experts was so conflicting that the case was decided against the Societies on side issues. An appeal will naturally follow; but, meanwhile, whether as a direct result or not, a new Society has been formed for the cultivation of Medical Jurisprudence, about fifty members of the Philadelphia bar and thirty physicians of prominence in that city having already expressed their desire to join the Association. This conjunction of the learned professions may be expected to work to the benefit of all concerned. The accustomed browbeating of experts will probably soon be a thing of the past now that the difficulties of scientific evidence are to be studied by the two professions side by side.

The Dwight case presents numerous curious features. It appeared from the evidence that, after obtaining policies for nearly four hundred thousand dollars, the insurer died very suddenly when he had only paid the first quarterly premium with borrowed money. A theory of suicide was brought forward, and contested. Creases were found in the neck, and variously attributed to strangulation and flexure of the body after death. Putting aside the evidence on this point as being too conflicting to allow of any conclusion, it is still unsatisfactory to find the case decided against the life insurance companies, when it was in evidence that the replies given to some of the questions in the original proposal forms were false and misleading. Life insurance is commonly, in this country at least, regarded as a legal contract, based on certain statements, the responsibility terminating should these statements be proved to have been wilfully incorrect. Those holding policies in American companies will do well to consider their risks, when a jury can decide in this way in face of the facts.

Nobody for a moment imagines that *everything* appearing in print is to be taken seriously, and regarded as literally true, still it may be doubted whether it is quite fair for a medical paper to play off on the general public elaborate jokes in the form of an editorial article. The *Philadelphia Medical News* has tried the experiment in a recent article entitled, "Shortening the Duration of Pregnancy." Much ingenuity is displayed throughout to develope the desirability and the possibility of interfering with the natural course of events, and advancing the time of delivery by two months or more. The writer is certainly not sanguine about the immediate acceptance of his suggestions, but he makes the bold claim of a discoverer, "when the practice is adopted let there be no dispute as to with whom, and when it originated." The time will come, he seems to say, when all fortunate beings, who have been saved two months and hard labour at the end, will turn with blessings to remember the author of an anonymous article in the *Philadelphia Medical News*, of January 26, 1884.

A taking title, a serious introduction, and references to such varied authorities as Baudelocque, Barnes, President Lincoln, the author of "Tristram Shandy," and the author or authors of "The Iliad," will hardly convince medical or lay readers, that the article is intended seriously. Granted, that from the mother's point of view, it may be desirable to shorten the duration of labour, the *couveuse*, described by Auvard, scarcely proves that it may be equally desirable from the infant's standpoint. At its best, the article is but a gross satire on the work and theories of obstetricians. If fatty degeneration of the decidua is to be regarded as the cause of labour, we are advised to use arsenic or other "steatogenous" medicine. If we believe in ovarian influence, faradisation of the ovaries is suggested. Further, for those who look to excessive distention of the uterus, "there ought to be no hesitation as to introducing a canula into the fœtal sac, and pumping in a sufficient quantity of warm water to excite uterine action." And all this is urged, with seeming gravity, to diminish the risks of lacerations of the maternal passages.

It may be that the satire is not wholly undeserved, but if this style of writing is to be on the increase in medical journals, may it not be well for the peace of mind of the non-professional reader, to have a separate

column headed "comic jottings," or even to begin by saying, "This is *meant* for a joke!" It would be too trying to be called upon to discuss the question with some lay friend, who had seen at his club an article on "Shortening the Duration of Pregnancy."

It is natural enough that Englishmen should be proud of their liberty, and excessively jealous of all interference by "outsiders." Every man's house is his castle, and although the necessities of civilization oblige men to hold "castles in common," still the various communities remain imbued with the spirit of exclusiveness, and bar their gates against strangers. Professions and trades prefer to manage their own affairs, and resent any interference from all who are not of the same calling. And a similar feeling of independence, tinged with exclusiveness, and somewhat poisoned by arrogant intolerance, is to be found in every small community, which has no other tie to bind it excepting the fact that the individuals who compose it inhabit the ill-drained houses which their forefathers built, and can appeal to the grave-stones in the parish churchyard as proofs of their membership. All over England the same kind of exclusiveness is to be found, and it is not only that county people in the provinces look down on those who are not "county," but every small village looks down with *modified* contempt and dislike on each neighbouring village and town.

There are, no doubt, degrees of hatred. One of Cooper's naval heroes expressed the descending scale of hatred very forcibly when he said "A messmate before a shipmate; a shipmate before a stranger; a stranger before a dog; but, a dog before a soldier." We think average provincial Englishmen would place "a Central Board" in the soldier's place—at the bottom of the list of objects of loathing; and the Boards know it. Nothing else can account for their timidity; nothing less can excuse their want of courage. The Boards, whose duty partly lies in making men healthy or keeping them so, address the communities supposed to be under their control with bated breath and whispering humbleness when they touch on sanitary matters. Last year the Board of Trade felt bound to call the attention of the shipowners to the fact that *for some years* scurvy had been on the increase in British ships! The Board ventured to suggest that the remedies were in the owners' hands, but they forbore to insist upon their use. The central authority contented itself with a vague threat, that if things went on from bad to worse it would be obliged to interfere in some distant "hereafter."

In that instance we suppose the Board of Trade did what it could; and now we must prepare to make the same charitable allowance for the Board of Health. It does what it can, and receives the usual treatment. We find in *Pulman's Weekly News* that the latest aggression has been in the West of England. The reporter heads his description "The Local Government Board Return to the Charge." It is worth while to notice the unwarrantable attack of the Government Board, and the gallant defence of the Board of Guardians at Axminster. The official letter is dated January 8, and is as follows:—"The Local Government Board have received a report from their Inspector, Mr. Courtenay, of his visit to the Axminster Union Workhouse, on the 20th of October last, in which he again draws attention to the defective accommodation for the sick inmates. He states that there are still several inmates in the sick wards that are not entered in the medical officer's books; while cases of ordinary disease are placed in the ward by the gate. The Inspector also reports that during a recent outbreak of measles the receiving wards had to be used for separate wards, and that at the time of his visit a vagrant suffering from itch was under treatment in one of the receiving wards." And then, after this annoying statement of defects, the Central Board proceeds to irritate the Guardians of the Poor at Axminster by hinting that some day or another it will be necessary to send down another Inspector, and write a very severe letter indeed. "The Board (continues the Secretary) direct me to inform you that, having regard to the repeated reports which they have received from their Inspector on this subject, they can no longer accept the responsibility of permitting the present defective arrangements to continue, and they must accordingly request the Guardians to take the matter into their serious consideration, and inform the Board of the steps which they may decide upon taking to remedy the defects referred to."

The reply of the Guardians, through their mouthpiece, the Chairman, was what might have been expected. "We have taken it into consideration *for many years past*," said the Chairman, "and shall do so again. (Laughter.) If it were not for that place Mr. Courtenay would have no report to make. *We keep it for his convenience.* (Laughter.) I don't consider that alterations are necessary, but I suppose we must consider the matter again." The subject was then referred to the Visiting Committee. Any person who jumped to the conclusion that the Guardians were hard-hearted or indifferent to the welfare of the paupers of Axminster would be completely in the wrong. They are merely utterly blind to the advantages of sanitary science, they have no belief in the prevention of disease, they despise all theories of infection and contagion, and they are roused to fury by the interference of a London Board. And yet it is the duty of that Board by steady pressure to ensure that the widest view of their duties should be taken by local authorities. The object of a Central Board is to provide for the comfort, health, and security of communities. It should act as eyes for those who are blinded by their own want of education, or narrow local prejudices. It should have hands, too, as well as eyes—hands which can make themselves felt by other action than that of writing polite letters of recommendation to local authorities.

Amongst the many reports of the Local Government Board Inspectors during the year that is past, that by Dr. Blaxall, on the continued prevalence of diphtheria in and around Taunton, is not the least instructive. The first case occurred in October, 1881, from which

time fresh cases appeared in each month up to December, 1882, invading in all 127 houses, with 215 cases, and 53 deaths. The sewerage and house drainage were found to be in a most unsatisfactory condition, whilst there was no efficient system of refuse removal. Further, the water-supply was inadequate, and Dr. Blaxall recommended that the works, in progress for increasing it, should be completed with as little delay as possible, so as to completely substitute the issue of town water for the questionable well supply still resorted to in many parts of the district. Dr. Blaxall was able to acquit water, milk, and sewer-air of having exercised any *direct* influence on the spread of the disease; and to decide that personal intercommunication between the infected and healthy was the only satisfactory solution of the problem. Abundant evidence was forthcoming that such intercommunication obtained to a very great extent. Personal intercourse took place freely between infected and healthy families, servants going to and from one to the other; females and children continuing to attend factories and schools while in an infective condition, or going there from infected dwellings.

At the same time there could be no doubt but that the unwholesome conditions existing in the town did indirectly conduce to the spread of diphtheria and its fatality by pre-disposing people to contract it and succumb to its effects; and its protracted presence extending over fifteen months, would seem to find explanation in the delay that occurred before any attempt was made to secure the due isolation of the sufferers. The first case received into the sanitary hospital was on the 6th of March, and up to the end of May only two more cases had been received, although the disease had been prevailing since the preceding October. The largest number of cases received into hospital in one month was nine, in October, 1882; and it is not unlikely that the subsequent speedy termination of the epidemic was related to an increased activity in securing isolation of the sufferers. In all probability, says Dr. Blaxall, had similar prompt action been taken at the commencement of the outbreak, the disease would not have assumed such widespread proportions. The lesson to be gleaned from the report is very important.

As a sequel to this report, Dr. F. H. Blaxall has published the result of his enquiries into outbreaks of the same disease which occurred almost simultaneously in the Taunton rural sanitary district. Whilst employed upon the first enquiry, he received instructions from the Local Government Board to visit any of the surrounding villages in which diphtheria was at that time prevailing, and he accordingly made careful inspections of the villages of Bishop's Lydiard, Bishop's Hull, and Bathpool. There is but little additional knowledge to be gained from the report under notice; the greater portion of these local board enquiries have long since established the fact that the country districts of England and Wales are lamentably deficient in sanitary requirements of every description; and, as we have before pointed out, but little real improvement can be expected so long as remedial measures are left in the hands of local authorities. It is not only that these latter are ignorant of even the first principles of sanitation, but they are utterly crippled by the prospect of incurring expense which ratepayers are certain vigorously to resist. The substitution of a really effective method of improvement for the country generally can only be brought about by means of legislation which would transfer the power of effecting radical reforms to the central board, the cost being borne by the locality benefited.

In the present instance Dr. Blaxall found in each of the villages inspected, that cess-pit privies of the worst type were general, and that the water supply was, for the most part, derived from wells greatly exposed to pollution. In two instances he was enabled to establish the fact that diphtheria had been introduced into the villages—in one case from the town of Taunton, in the other from a neighbouring village—but there was little doubt that the condition of the localities themselves favoured the spread of the disease when once it had been imported. The excremental nuisances met with in the several villages, the report says, are no doubt inseparable from the method of excrement disposal that is employed in this rural district; and it is highly important, it adds, that a wholesome method of removal and disposal should be introduced, and the existing privy pits abolished; it is moreover suggested that the dry earth principle would probably be found well adapted to meet the requirements of the district. Further, steps should be taken to secure to the people a plentiful and wholesome supply of water which, where practicable, should be brought into the villages from extraneous sources.

"Generally speaking, the past year has been a satisfactory one;" such is the remark of Mr. Karkeek, the Medical Officer of Health for Torquay, in introducing his annual report for the past year. The death-rate for the period—16·9 per 1,000—has, nevertheless, been somewhat above the average of the previous nine years, and includes 56 cases of phthisis, and 76 of bronchitis, pneumonia, and pleurisy. It is satisfactory to learn that the Torquay rulers have at length provided their Medical Officer with the means of fighting against infectious disease, and the sanatorium which has been for so long a time promised, is actually furnished and in working order. Mr. Karkeek has been engaged in ascertaining whether there is much overcrowding in the town, and although he has not yet finished his labours in this direction, he has satisfied himself that the close packing of Torquay is unaccompanied with the immoral surroundings found to exist in most large towns.

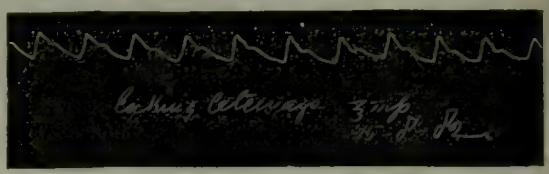
We have much pleasure in drawing the attention of our readers to the following resolution, passed at a meeting of a committee recently appointed. It runs as follows:—"That subscriptions be asked for the purpose of placing in an appropriate position in Guy's Hospital, a bust or other memorial of the late Dr. Hilton Fagge;

and that any surplus of the amount raised, be devoted to aid in the education of his children." Subscriptions may be sent to the treasurer, Dr. Wilks, 72, Grosvenor Street, London, W., or to either of the honorary secretaries, Dr. Frederick Taylor, 11, St. Thomas's Street, S.E.; and Mr. Charters J. Symonds, 16, St. Thomas's Street, S.E.

In the current number of the *Journal of Anatomy and Physiology*, Dr. B. C. Windle publishes three cases of sarcoma of the kidney, and tabulates all the cases he has been able to find. According to the state of the remaining portion of the kidney, he divides the cases into three groups:—In the first the growth commences at the hilus, and spreads on the inside of the pelvis in every direction without invading the proper structure of the organ. In the second group the growth invades the kidney in the course of the blood-vessels between the pyramids. In the third group the growth commences at the hilus, and spreads along the outer surface of the capsule, thus enclosing the kidney in the centre. In the same journal, Mr. A. W. Hare, gives a new method for determining the position of the fissure of Rolando in the living subject. From a study of eleven skulls, he found that the distance from the glabella to the fissure was on an average 55·7 per cent. of the distance from the glabella to the occipital protuberance within very narrow limits. This promises to be a very easily applied rule, we hope it may prove reliable.

In previous reports on the sanitary condition of the Wandsworth District, the subject of uncertified deaths has been commented upon, owing to their prevalence in that locality; it is, therefore, satisfactory to find from the report for the year 1882, that the number of deaths not certified by medical testimony, which had so greatly increased during the year 1881, underwent a very considerable reduction: the figures showing 96 for 1881, against 67 for 1882. It is scarcely necessary to repeat, the report adds, what has been so frequently urged, namely, that this laxity in the registration of deaths requires an amendment of the law, by which the cause of death shall be made in every instance an ascertained fact, as far as human knowledge can make it so. In such view of the case, it may be observed that if in all cases in which the cause of death has not been certified by a registered medical practitioner, a preliminary medical examination were substituted for the unskilled inquiry of the coroner's officer, a large number of the inquests which are now needlessly held might be dispensed with, at the same time that the object of the coroner's court, and consequent security to life, would be more completely attained. This course of procedure would appear to have been adopted in the West Battersea portion of the district, to a certain extent, and, as a result, the return of the number of inquests in that portion shows that 39 were held during the year 1882, as compared with 63 during the year immediately preceding it.

"J. K. B." sends us a sphygmographic tracing of Cetewayo's pulse, which was taken by him when the late Zulu King was living in the Melbury-road. The circumstances under which Cetewayo is reported to have died sufficiently excuse us from breaking through the rule of the *Medical Times* not to report upon the illness of personages, *quâ* personages. "J. K. B." writes:—"As ex-King Cetewayo is stated to have died suddenly of fatty degeneration of the heart, it may interest your readers to know what was the state of his heart when he was in England in August, 1882. In auscultation the heart sounds were absolutely normal, and the appended sphygmographic tracing will show the



healthy state of the arterial system. Cetewayo's main ailment, when in England, was constipation from excessive meat diet, combined with want of exercise."

PUBLIC OPINION AND EXPERIMENTAL PHYSIOLOGY.

I.

The claim put forward by Mr. Freeman in his remarkable speech at Oxford, and reiterated by him in a letter to the *Spectator*, to regard his special study—history—as a branch of science, and himself as a scientific man, makes one vividly realise the danger that always attends success. Science was for ages the Cinderella of the family of knowledge, contemned and scouted by all her sister studies, and now that after long years of patient and conscientious work she has at length achieved fame and recognition, she finds her old persecutors flocking round her to claim a share of her prestige. It is a danger to be guarded against. For while science will gladly see the workers in other studies putting on the scientific spirit, and imitating her painstaking observation and rigid processes of inference, she must firmly protest against their claiming a position to which they have no right. With all due deference to Mr. Freeman, science does not, in the common acceptation, "simply mean knowledge." For the vast majority of people it means "natural science," the study of the laws which govern natural phenomena; and it is an unwarrantable extension of language, and certain to harm the respect in which the term is now held, to apply it to branches of study which have very little prospect of ever being able to attain to that certainty of prediction which is the mark of a science properly so-called. Mr. Freeman, in his letter to the *Spectator*, compares the sciences of history, geology, and physiology. In each, he says, men follow the pursuit for its own sake, and just as zealously whether it leads to any practical result or not. If it does, so much the better; if not, the worker has improved his own mind. But in the two former he has done no harm to man or beast, a claim which the physiologist cannot make. "We are told," says Mr. Freeman, "that this kind of knowledge, *i.e.*, physiology, like the other two, has its practical use in the improve-

ment of the art of medicine. But it is as certain, as in the other two cases, that the votaries of this branch of knowledge follow it for its own sake, whether it leads to such practical results or not. They say, like the historians, that their study is good in itself and improves their own minds." That is a travesty of the opinions and claims of cultivated physiologists, and of the members of the medical profession, who, we are convinced, would be quite as much opposed to vivisection as Mr. Freeman is, if its main object were merely the mental culture of the individual worker. The claim consistently put forward by the physiologists is, that vivisection is justified by the prospect of the knowledge gained by it contributing to the relief of suffering and the prolongation of life. They admit that the practical application of any particular research may not be immediately visible, but they point to innumerable instances in which discoveries, apparently useless at the time, have led to the most far-reaching and beneficent practical results, and they proclaim that there is no item of physiological knowledge, which is not certain sooner or later to be found useful in practice. But to state that vivisection has ever been justified by any responsible representative of science on the ground of self-culture, is little short of an ignorant libel. Science has not yet sunk to such a level of priggish self-consciousness as that.

Where an intelligent man, like Mr. Freeman, so thoroughly misconceives the attitude of the scientific school, it is hardly to be expected that the ordinary lay public will show a truer insight. The vote at Oxford was extremely satisfactory to all who have the welfare of science at heart, but still it is evident that public opinion is very ill informed on the merits of the question. Reasonable men on both sides are content to abide by the decision of Parliament, but as the extreme party amongst the zoophilists still scout all idea of a compromise, the whole battle of vivisection—of its sanction and its value in any circumstances and under any restrictions, or its absolute uselessness, and, therefore, logically, of its total abolition—must continue to be waged; and every member of society who takes an intelligent interest in the mysterious vitality which he shares, and by virtue of which he suffers, in common with the whole animal world, must still hold himself liable to be drawn into the contest. Few men, and perhaps still fewer women, pass through a year of life, without often having their attention directed to some aspect of the subject, and without being called upon to go through that process which they term making up their mind upon it, or, at all events, upon some one of its many practical applications. To medical men, the question, of course, frequently presents itself. The results derived from the practice of vivisection (using that term in its broadest signification) are so continually adduced to strengthen or to confute previous conclusions; to give weight to some new discovery; or to indicate the probable existence of a hitherto unsuspected danger—that every practitioner, if he be not actually crystallising, comes to regard it as at least a recognised method of research. And in the mind of every man whose end is scientific truth—the attainment of which he knows must redound to the benefit of his profession, of his patients, and of himself—there is a natural disposition to receive with hearty welcome any procedure which comes in the guise of a potent and valuable ally.

It is at this point that the discord rises loud and shrill. For there are those who contend, with a pertinacity and vehemence which are in themselves sufficient to command assent in many minds, that this aspect of vivisection is a *dis*guise, and that all and every the results which it has achieved are not merely useless, but absolutely misleading. There have, it is true, been violent champions on both sides; and the medical profession is itself to some extent responsible if, on this question, its opinion is not accorded that full weight which it might have been expected to secure. Activity and energy are of the greatest value in promoting and sustaining any movement: but dignity as well as strength is necessary if we would command respect; whilst caution, tact, calm judgment, and courteous consideration for the sincere—even though mistaken—feelings of our opponents, will do far more, in the long run, to disarm opposition and secure success, than a front of bluff and brutal assertion. We do not wish it to be understood that, in our opinion, this latter represents the position which has been taken up by the profession as a body upon the vivisection question: but the noisiest orators are too often accepted by their audience as the typical exponents of their party's views; and it cannot be denied that if the arguments advanced by the anti-vivisectionist are sometimes not merely wanting in accuracy but absolutely baseless, the replies by which they have been met have been too often violent and inconsiderate. One result is that all the members of a humane and self-denying calling are, in the eyes of the general public, branded with the same extravagant partisanship which has been exhibited by a few: and a second result is that every medical man is expected to respond to any challenge from chance combatants, and to be prepared to do battle *à outrance* in defence of every item of the extreme creed with which he has been credited. No doubt the public are themselves largely to blame for the mistakes into which they so readily fall. It is so much less trouble, and often so eminently self-satisfying, to believe the whole charge rather than take the pains to examine and dismember it, in order that one may finally accept no more of it than is really proved: and people will not take the trouble to assure themselves, for instance, that the vast majority of medical men are decidedly opposed to making legal the performance of vivisection by every young student or new-fledged graduate — or indeed by anyone — without the imposition of any restrictions whatsoever. The practitioner of medicine,—gentle and kind-hearted though he be, and firmly as he believes in the active humanity of his professional brethren—is also a man of intelligence and experience: and he knows that there is "a great deal of human nature" (humanised brute—not brutal—nature is what that phrase really means) in man—far too much, in fact, to make it wise or safe to free every investigator from every restriction. Nor will the public pause to study the signification of the term which it abuses. For most, "vivisection" means—vaguely but terrifically—"experimental torture of living animals;" and it is a matter of little or no moment that, in eight cases out of ten at least, suffering is prevented or minimised in the present by a previous narcosis, and

obviated, as regards the future, by a painless death; while the possibility as to whether the result of such an experiment may not be to achieve a lasting and valuable boon to humanity at large, is one which is usually ignored.

The effort of thinking and working out a subject, which to an active and well-nourished brain gives such pure delight, is an irksome and repulsive toil to the comparatively unexercised organ which fills the average cranium, especially where the result appears to be of a problematical or abstract character. It is so easy to agree to the propriety of having the surface neatly raked to its wonted smoothness: it requires so much more trouble to prove whether or not real good will follow the apparent desecration of our flower beds by the rude steel which turns up rugged but rich clods of earth from the unthought-of depths below. And this moral laziness wears a specially seductive garb, for it appeals not only to man's natural dislike of trouble, but also to his desire for respectability: it says, as it were, "By adopting these views in their entirety, you not only escape the labour of threshing out arguments for your own use, but you will have put into your mouth the ready-made pleas which have been accumulated by generations of the most kind-hearted and sincere of both sexes; and you will range yourself with the party which represents all that is refined and humane in Christendom, as opposed to that which feels and exhibits no compunction and no pity for any of the suffering involved in the prosecution of its own selfish aims." Comparatively few average folk have the moral caution and energy to resist pleading like this—which is all the more insidious because it is never couched in quite such plain language. They have always heard kindness to animals inculcated as a moral duty, whose exercise is especially distinctive of the true gentleman; they would themselves shrink from—and they say, and persuade themselves, that they are always careful to prevent—inflicting any avoidable pain upon the lower animals; and because the mere statement even suffices to make them conscious of something like a moral glow, they forthwith accept the proffered deduction, that the intentional infliction of pain for any purpose must be immoral, and therefore unjustifiable; and so sink back comfortably, content with having solved the difficulty in a manner which is quite satisfactory to themselves, and morally elevating to all concerned. They are firmly decided against re-opening the question upon any ground; they will now do nothing beyond re-asserting the conclusions at which they have arrived—or rather, which they have accepted. It never occurs to them that there can be any question of testing the basis-value of the arguments upon which they rely; they would scout the notion of according a deliberate and impartial examination to those of their opponents; and, above all, they do not entertain a doubt as to being themselves completely qualified, by the necessary practice, observation, and experience, to accurately gauge the value of every piece of evidence adduced on either side. The best of people are liable to be influenced in this way. Not long since the chairman of a meeting at which the question of the justifiability of vivisection was under discussion—a medical man of varied and distinguished attainments—ventured to deliver himself of the opinion, "that no man was ever justified in inflicting pain upon one of the lower animals in order to the attainment of his ends:" which provoked the obvious question, whether he was always prepared to put that principle into practice; whether, for example, if he had received an urgent summons from a patient at a distance—who was represented as being in imminent danger, which the surgeon's presence might be expected to avert or to relieve—he would still feel bound to abstain from using whip or spur as an aid towards speeding him to the rescue? "You have no right," some of these good people say—"even if your results were all that you profess—you have no right to claim that the 'end justifies the means;' it is a Jesuitical and a fallacious precept." And yet upon the general acceptation of this maxim hinges half the business of life, and more than half the possibility of modern civilization. Arguments that are obvious and old are not, on that account, necessarily worthless; and those who sanction the death of millions of sentient beings that they may be—sometimes merely that they may be luxuriously—fed and clothed; who consent to the daily performance of painful operations upon domestic animals for the sake of increasing their value as food, or their docility as beasts of burden—not to mention those who subject whole batches of half-tame birds and timid beasts to wholesale slaughter by a painful and too often lingering death, in the pursuit of so-called "sport"—such persons have no right to say, with respect to the deliberate infliction of suffering upon animals, that in no case does the end justify the means.

And do the people who argue thus ever have the extreme courage of their opinions—that is, when courage is the test? We have never yet heard of an anti-vivisectionist who, in the hour of need, and upon the grounds of a logical and conscientious objection to their origin, refused, either for himself or for his friend, to take advantage of one of the many methods and improvements which are admitted to have been brought at least within the range of practical therapeutics, through the knowledge attained by vivisectional experiment. Such professions, made before the trial, have indeed appeared in print; but there is no evidence that those who made them have elected to submit to medical or surgical treatment in accordance with a system from which had been expunged all the hygienic precautions, all the methods, all the drugs, all the manual and diagnostic delicacy, all the knowledge and experience which, through century after century, have been accumulated, corrected, corroborated, classified, and made available for intelligent application to the human patient, by experiments upon living animals.

CHARITABLE BEQUESTS.—The late Mr. James Benjamin Ball, of Dublin, has left 1,000*l.* each to the Adelaide Hospital, Mercer's Hospital, the City of Dublin Hospital, and the Rotunda Lying-in Hospital; 500*l.* to the Whitworth Hospital, Drumcondra; and 300*l.* to Combe Lying-in Hospital. The late Mr. W. T. Smart, of Brighton, has left 100*l.* to the Sussex County Hospital; and the late Miss Catherine Cain, of Southport, has bequeathed 100*l.* each to the Children's Infirmary, the Lying-in Hospital, and the Royal Infirmary, of Liverpool.

RECENT RESEARCHES ON THE PATHOLOGY OF PNEUMONIA.

For a long time there has been a growing tendency to emphasize the many points of resemblance which acute idiopathic pneumonia presents to the infectious fevers. The acute onset generally marked by a rigor, the well defined constitutional symptoms, the general tendency of the disease to come to a crisis on or about the seventh day, remind us so strongly of the acute fevers; that we are led again and again to consider whether pneumonia ought not to be removed from the group of simple inflammations and transferred to that of the acute infectious diseases. There probably exist few old practitioners who have not been often puzzled at the outset of a case of pneumonia, as to what was the nature of the disease they had before them, it being a matter of doubt whether the case were one of small-pox, typhoid fever, or even of erysipelas, in that rarer form in which constitutional symptoms appear for a day or two before the rash. After a period of from one to four or even five days, the occurrence of signs of local inflammation, extending over a varying portion of one or both lungs, clears up the doubt, yet at first a certain diagnosis has been impossible. The one great reason against classifing pneumonia with the infectious fevers, is of course that in England, at least, it appears to be non-infectious; and yet puzzling outbreaks of several simultaneous cases of pneumonia amongst persons inhabiting the same house or room have been placed on record, and this usually in places where the sanitary arrangements are so bad that enteric fever and erysipelas are also liable to be epidemic. The fact, moreover, that another lung disease, tubercular consumption, still generally considered to be non-infectious, has been traced to a micro-organism, by the inoculation of which it can be produced at will, materially diminishes the force of the argument just quoted, and cannot fail to merit considerable influence on the minds of those who are searching for a more satisfactory explanation than is at present available of the pathological phenomena of pneumonia.

Bearing all these facts in mind, we have noticed with much pleasure two able scientific papers which seem to have a considerable bearing on the problem. The first is an account of some observations on the pneumonia of the Punjaub frontier, by Surgeon George M. Giles, published in the Appendix to the recently issued report of the Army Medical Department for 1881; the other is a paper on the infectious nature of pneumonia, by Martin Mendelsohn, which appeared some weeks ago in the *Zeitschrift für Klinische Medicin*, 1883. Both of these papers seem to us to be of very great importance, and both appear so far to have met with less attention than they deserve. The report of Dr. Giles gives his observations of five cases, and the results of some experiments made on rabbits. The form of pneumonia described by him differs in many respects from the form met with in this country. It appears to be more of the nature of broncho-pneumonia, though always attended, with pleurisy; and it has a somewhat longer duration than the disease with which we are familiar: the crisis coming on the eighth, ninth, or tenth day. Yet, on the whole, the sudden onset of the illness, the high temperature and constitutional symptoms preceding for a short time the development of pulmonary consolidation, the sudden fall of temperature at the crisis, followed by the gradual resolution of the consolidation of the lung, and lastly the nature of the expectoration, all remind us so strongly of ordinary pneumonia that we are compelled to regard it as a variety, and not as an essentially distinct disease. The most interesting part of Dr. Giles's paper lies in the fact that he has proved that in all his patients a peculiar micro-organism was present both in the blood and sputa during the whole of the illness, that these micro-organisms were similar in all the cases in which they were looked for, and that when sputa containing these were injected into rabbits, they, too, were also attacked by pleuro-pneumonia, to which they succumbed; and that the blood pleuritic effusions and lungs of the rabbits were found to be crowded with numerous similar organisms. The paper shows clearly how much an able man can do towards clearing up the nature of a disease, even though the apparatus at his command is very elementary. The paper shows that a form of pneumonia, closely allied to our ordinary acute pneumonia, is in all probability due to the presence of micro-organisms in the blood and lungs, and that the same disease can be conveyed to rabbits, at least, by inoculation; also that, in the opinion of good observers, the pneumonia occurring on the Punjaub frontier is infectious.

The paper of Dr. Mendelsohn, who has had all the advantages of a hospital and laboratory, with suitable apparatus, treats of the ordinary European form of pneumonia. Dr. Mendelsohn firmly believes, that this disease is infectious in its nature, that it depends on the presence of bacteria, and that one form of bacterium is constant in all cases. He has divided his paper into seven sections, and we cannot do better than briefly indicate the several contents of each. The first treats of the epidemic outbreak of cases of pneumonia. The author has collected observations, proving that numerous cases often occur simultaneously in small districts, sometimes among the troops stationed at one place, sometimes in private houses and prisons; and he shows in his next section that these epidemics can often be referred to miasmatic influences, especially in connection with bad sanitary arrangements and deficient ventilation. In the third division of his paper, he has collected numerous cases of apparent infection of one person from another, and he shows that not only are those in immediate connection with the sick in danger of taking the disease, but also that it appears capable of being carried from the sick to others by persons who do not themselves contract it. He next deals with the prevalence of pneumonia, which he shows to be independent of changes of temperature, but to vary with the amount of rain and the consequent rise, and the fall of the subsoil water. The fifth section treats of the micro-organisms of pneumonia. The cause of the disease is, in Dr. Mendelsohn's opinion, probably the bacterium described by Klebs as monas pulmonale, which Leyden and Günther were the first to obtain, by puncturing the living lung. These micrococci are egg-shaped, and generally occur

in pairs, but also in chains of three or four. Similar but larger forms are found in the pleuro-pneumonia of horses. Next, Dr. Mendelsohn states that the time of incubation appears to be about twenty days, and he places pneumonia in that class of infectious diseases, one attack of which predisposes to a second. In infected places strangers are more liable to be affected than natives, and a state of tolerance of the poison appears to be gradually developed. The last section treats of the unity of the poison. One cause lies probably at the root of all cases of pneumonia, the differences in the symptoms in different cases depending on the amount of the poison and the power the individual has of resisting it. Drunkards are especially liable. Exposure to cold is a favouring, not an exciting, cause.

On comparing these papers, we are struck with the points of resemblance which run through both, and especially with the importance assigned by both authors to the bacteria they found. It is also noteworthy how similarly these bacteria have been depicted by both—egg-shaped bodies occurring singly or in short chains. We can only hope that the question, how far these organisms are universally present, may be answered by observers in other countries, and that where they are found experiments may be made, if possible, on rabbits or other animals to determine how far the differences in the symptoms of pneumonia in different parts of the world depend on slight variations of the specific micro-organism. It is a field of enquiry at present almost unentered upon, which, however, more than any other holds out the hope that we may be able, if not to treat pneumonia with any greater certainty of cure, at least to remove, as far as possible, all causes likely to produce it.

REVIEWS AND NOTICES OF BOOKS.

RECENT BOOKS ON DISEASES OF CHILDREN.[1]

The justifiable claim of diseases of children to be regarded as a class by themselves is almost exclusively based on clinical considerations. Strictly speaking, this department of medical study cannot be called a specialty, nor is it in any way comparable with those branches of practice which alone deserve this appellation in the best sense, from requiring some special manipulative skill in the application of diagnostic methods and in surgical treatment. From the pathological point of view, diseases of children are obviously an integral part of general medicine, and only those who possess general medical knowledge can rightly study or successfully treat them. But there are many maladies which are especially incident on childhood, and others whose symptomatology is at that period peculiar, not to mention the physiological characteristics due to the rapid development going on in early life, and some practical difficulties in those methods of diagnosis which are open to us. There is, therefore, not only a justification, but an absolute necessity for the existence of works on the subject from the pens of those who, in addition to a sound medical knowledge, have had a large personal experience.

The first book on our list fulfils these requirements in a manner as rare as it is praiseworthy. It is marked throughout by a consistent adherence to the subject in hand, and a thorough treatment of it, which, while of the utmost use to the student, must compel the admiration of the most experienced practitioner. We miss altogether the initial padding so common and so useless in German books; from the first to the last the matter is rich in value, and there is scarcely an unnecessary phrase. It is indeed quite refreshing to read a work devoted to diseases of children, without having to wade through a practically useless list of statistical averages and anatomical details, and a superfluous, though generally for its ostensible purpose inadequate, réchauffé of pathological facts and theories not peculiar to the material treated of.

Professor Henoch plunges at once into his subject, and those who have any share of his great clinical knowledge will recognise a master-hand in all his work. The book is almost entirely, as the author says, the product of personal experience, and this necessarily lends it a very uncommon value. Thirty-seven years experience must give a careful observer and a clear expositor a good right to teach his fellows: and after a careful perusal of these lectures, we must unhesitatingly say that there is more sound practical knowledge to be derived from them than from any one work on the subject, however good in style and encyclopædic in nature, with which we are acquainted. We can only hope that the merits of this book will, before long, produce a second English edition, in which certain inaccuracies and inelegancies in translation may be avoided, and the dosage and names of medicines may be adapted to English use. One apparently very grave error in figures, probably due to the printer, occurs in the chapter on "Convulsions in childhood," where, on p. 70, the dose of hydrate of chloral is stated to be from 1·0 to 2·0 to 100·0 (!) internally. (The numbers throughout the book apparently denote *grammes*, though this, in an English translation, should have been especially stated.)

It would be impossible, in the short space of this notice, to illustrate adequately the merits of our author's teaching. Everywhere we find traces of extended observation, and remark the absence of those familiar but uncorroborated statements of facts and fancies which in medical literature are so often copied from book to book. It must suffice to quote a few points in illustration. Dr. Henoch, though regarding *craniotabes* as rachitic, examined hundreds of cases, and but rarely found them as described by Elsässer. *Tremor* as a convulsive symptom in young children is noted as being rare, and almost solely due to cerebral tuberculosis or meningitis, or other diseases of the brain, with paralysis or contracture of the limbs. The

[1] Lectures on Diseases of Children. A Handbook for Physicians and Students. By Dr. Edward Henoch, Director of the Clinic and Polyclinic for Diseases of Children in the Royal Charité, and Professor in the University of Berlin. London: Sampson Low, Marston, Searle, and Rivington. 1883.

The Diseases of Children. A Handbook for Practitioners and Students. By Armand Semple, B.A., M.B. Cantab., M.R.C.P., Physician to the North-Eastern Hospital for Children, &c. &c. London: Baillière, Tindall, and Cox. 1884.

The Wasting Diseases of Infants and Children. By Eustace Smith, M.D. London, F.R.C.P., Physician to the East London Hospital for Children, &c. &c. London: J. and A. Churchill. 1884.

remarks on "Spinal Paralysis in Childhood," are of much value: though the author may hereafter see fit to correct his statement that "spastic spinal paralysis" does not correspond to any definite anatomical change. In the present state of knowledge on this matter the possibility of such correspondence should at least be referred to. In the section on Nervous Diseases, we would especially point out the chapters on *Convulsions*, *Hysteria*, *Cerebral Tuberculosis*, and *Meningitis*, as full of useful instruction, and would lay stress on the welcome absence of a gratuitous and scholastic differential diagnosis of "epilepsy" in early childhood. It is better, considering the physiology of this subject, to confess a difficulty in diagnosis than to teach a practically misleading dogma. Under the heading of "Diseases of the Respiratory Organs," the treatment of bronchitis and broncho-pneumonia together is specially to be commended: the clinical, and indeed anatomical, continuity of the affections being constantly and unaccountably overlooked in most books and many lectures. In the chapter on Tuberculosis (p. 166) we find a statement with which most observers who follow their cases to the post-mortem room will probably agree, viz., that the diagnosis of enlargement of the bronchial glands during life is extremely problematical. The lecture on Diphtheria is of great importance; and, apart from moot pathological questions, seems to us at once one of the clearest and truest expositions of the disease that we have seen. But the book must be read and re-read to be duly appreciated. There are but a few points to which exception might be taken: and some of these may be due to the different characteristics of some maladies in Dr. Henoch's field of observation from those seen in England, or to a faulty translation. The statement that paraplegia is almost always present in "chronic hydrocephalus" certainly seems to require revision: and many will question the teaching that choreic movements are *always* increased on volitional effort. Many English observers would probably consider intestinal perforation in fatal cases of typhoid fever in children as more common than Dr. Henoch does, and would lay more stress on the not infrequent acute beginning of this disease. The author rightly accentuates the want of proportion of the nervous symptoms to the temperature in children's typhoid; the frequency of relapses, and of vomiting, and the minor importance of cæcal tenderness and gurgling; the only real fault indeed that we might point out in this very full and instructive chapter being one of omission: no mention being made of the obstinate and often distressing constipation which is so frequent in convalescence, and, being often accompanied by a rise of temperature, hinders us sometimes, in dread of a relapse, from promptly taking the right measures for its relief. Sound clinical knowledge will certainly be increased by the success of this book.

Dr. Semple's book is characterised by most of the faults whose absence from the above work we have already emphasized, and by a lack of all its virtues. It contains much superfluous and inaccurate matter, and appears to be mainly an unequal compilation from other works. On page 4 we read that in infants the pancreas and salivary glands are especially active; on page 38, that the saliva does not appear till the third month. On page 9, the infant constitution is said to be "decidedly nervous," while on page 21 it appears "that the nervous temperament is more especially manifest at or after seven years of age." Those of any clinical experience whatever, will be "surprised to hear" that the temperature is a reliable guide "in young children;" that some abnormal condition (if indeed the author attaches any *practical* meaning to the word abnormal) must be expected from a temperature above 100° or under 97°, or that the thermometer *alone* will indicate the suspicion of scarlet, enteric fever, &c. In all but very experienced hands the thermometer is often exceedingly misleading in the diagnosis of children's maladies. Several of the author's remarks on the treatment of alimentary disorders seem to be as crude and ill-digested as the commoner causes of many of the maladies whose relief they profess to teach. We are told, moreover, under the heading of intestinal obstruction, that when the diagnosis is doubtful, purgatives are to be given, but that when it is certain, purgatives are injurious; and that the treatment is the same in intus-susception. Jaundice is put first among the symptoms of hepatic cirrhosis, and paracentesis is said to be a "last resource" in the treatment of ascites. Further on it appears that ascites in children is most commonly caused by cirrhosis of the liver—a statement astonishing to the clinician and the pathologist alike. No mention is made of calculus in connection with hæmaturia, the only causes of this symptom noticed being purpura, scarlatina, and tuberculosis. Such an omission as this is but one fault out of many which justifies our opening criticism of this book. We should not say that aortic disease is "exceedingly rare in children," rheumatic endocarditis causing it quite as often, proportionately, as it does in adults; and but few who have had experience in aspirating for pleurisy would agree that it is necessary to make an incision in the skin before tapping, or that it is *always* advisable, even in ultimately incising the chest, to place the child under an anæsthetic. Apical pneumonia in children is too frequent and recovery therefrom too complete to justify the remark that it is an indication of a delicate constitution. Nor is it a general belief that salicylic acid should be given in rheumatism *after* the intensity of the fever is lessened. This book verily abounds in error and confusion. The important subjects of laryngitis, diphtheria, &c., are treated most inadequately, no clinical picture of the affections being given. These chapters can be of no practical use. The remarks on nervous diseases are very imperfect, and thrown about in a most disorderly manner, regardless of relative importance. We are told prominently that "Duchenne's paralysis" is more common in the rich than the poor, but are not taught what muscles are affected. Under "chorea" it is stated that the disease is *mostly* limited to one side, that there is usually derangement of the stomach and bowels, that it may be caused by irritation of the spinal cord or its membranes; and this inaccurate teaching is aggravated by the remarkable omission of all mention of heart-murmurs in connexion with chorea, and, under the heading of pathology, of the minute vegetations so often found on the mitral valve in fatal cases. The account

of the fevers is in keeping with the rest of this book, the chapter on typhoid presenting a remarkable contrast with the writing of a clinician like Dr. Henoch: for, however great the experience of the present author may be, we can find but scant traces of it in any part of this book, which is too erroneous and imperfect clinically to be of use to the serious student of medicine, or even to be a safe guide to him who aspires only to the position of a successful examinee.

The last book on the list requires but few words of praise at this late period of its deservedly successful career. It has now reached its fourth edition: and must be admitted by all who study it and follow its precepts to be a safe guide to the management of the diseases of which it treats. The many hints frequently occurring as to the preparation of food for children, and the diet-tables at the end, are not the least valuable part of the book, which in many minor points contains improvements on the previous edition.

The Pedigree of Disease; by JONATHAN HUTCHINSON, F.R.S. London: J. & A. Churchill, 1884.—This little volume contains the six professorial lectures delivered by Mr. Hutchinson at the College of Surgeons in 1881. The subject chosen will be admitted to be one of great importance, and one which cannot be safely ignored if our prognosis is to have a real value, or our treatment to be comprehensive, and yet it is one which has been strangely neglected, during the last quarter of a century at any rate. This we must attribute partly to the more minute study of disease-processes which our modern instruments of precision have rendered possible, and partly to the fact that the study of pathology is so much more fascinating and apparently so much more remunerative than the abstract contemplation of inherited or inheritable proclivities. In the first two lectures, Mr. Hutchinson deals with temperament and idiosyncrasy. The former must not be confounded with diathesis. Temperament is the sum of the physical peculiarities of an individual, exclusive of all definite tendencies to disease, and it is consistent with the prolonged enjoyment of perfect health. Diathesis is any bodily condition, however induced, in virtue of which the individual is, through a long period, or usually through the whole of life, prone to suffer from some peculiar type of disease; diathesis may be inherited or acquired, its effects may be permanent or constant, transitory or recurrent. The term diathesis indicates the proclivity to disease, while dyscrasia indicates actual bad health. In attempting a classification of the different forms of temperament, we have scarcely any other criterion than complexion, and peculiarities of complexion may almost be reduced to a question of the presence or absence of pigmentation. "Temperament is made up from two sources:—1. The hereditary transmission of peculiarities incident to race and family, which for the most part entail no morbid proclivity whatever. 2. Some one or more of the various causes of disease acting perhaps through many generations." The definition of idiosyncrasy, adopted by Mr. Hutchinson, runs as follows:—"It is to a large extent nothing but diathesis brought to a point. It is peculiarity of constitution in some one particular feature developed to a height, which, at first sight, seems inexplicable, and possibly almost absurd. It is individuality run mad." The term is never applied to acquired peculiarities. An idiosyncrasy is congenital and persistent, though it may become modified. It is well shown in such diseases as ichthyosis, xanthelasma, and in reference to certain articles of diet — *e.g.*, eggs, fish, tea — which to certain people under varying conditions may be absolutely poisonous. Tobacco amaurosis and arsenical herpes are both instanced as cases where, without idiosyncrasy, the disease would not be produced. The third lecture deals with idiosyncrasy in relation to drugs—*e.g.*, chloroform, iodides, and bromides—then with its effects on the progress and development of the specific fevers, notably of varicella and syphilis; and next an endeavour is made to show that there are certain conditions which may give proclivity to diphtheria, erysipelas, or carbuncle. This lecture concludes with the following remarks, which Mr. Francis Galton has just done his best to give practical effect to, viz.: "If it should become the custom for parents to record some sort of life-history of their children in permanent form from the birth or infancy onwards, noting all the peculiarities in an individual by the aid of medical observation, not only would much be done in the way of preventing subsequent errors in the treatment of disease, but valuable contributions would be made to our knowledge of its real nature." In the fourth lecture, Mr. Hutchinson speaks more especially of diatheses, making an important distinction between those due to food and those dependent upon climate; the latter are distinctly restricted and endemic, affecting all immigrants who come within their range, and under certain circumstances leave scarcely any exempt. The former are not endemic, they are persistent constitutional conditions, sometimes hereditary, at others not so, which have their origin in connection with food; gout and leprosy are instanced as the types of this form, scrofula and rickets being also in great measure probably food diatheses. This lecture concludes with some remarks on inherited syphilis and the laws which govern its inheritance. In Mr. Hutchinson's view it is not a diathesis which results from the disease, but the germs of the disease itself which are transmitted. In the two last lectures Mr. Hutchinson deals with the relation of pathological habit to diathesis, taking as illustrations of this erysipelas and elephantiasis; he likens the tissues in these affections to a drunkard, who, after each drinking bout, is more liable to an outburst in the future. Very often a diathesis may remain latent until disclosed by certain *revealing* or retrospective symptoms, such as eczema or acne. Iritis, too, he quotes as often the first indication of the gouty diathesis in young adults. Lupus is regarded as the result of an admixture of tendencies to scrofula and cancer, using the latter in its old and wide meaning of malignant disease, and not according to its more modern and more strict pathological interpretation. The catarrhal, rheumatic, gouty, and hæmorrhagic diatheses are in turn dealt with, the last named being regarded as not independent of gout. In concluding this brief notice we will only say that every thoughtful practitioner will read these excellent lectures with profit, and we doubt not with great interest.

Illustrations of the Influence of the Mind upon the Body in Health and Disease. Second Edition, 2 vols., crown 8vo.; by D. H. TUKE, M.D., &c. J. and A. Churchill.—We are glad to welcome a second edition of this interesting and useful book. Consisting, as it does, mainly of records of instances of the occurrence of bodily changes sequent on mental events, and enunciating no important principles to bind the facts together, the book offers little occasion for criticism. Many new facts have been recorded, and the chapters on Physiological and Psychological Principles have been in part rewritten. One of the new facts concerns Dr. Tuke's own experience, and as there can be no doubt of its authenticity, and as it is a very striking one, it may be quoted. He was about to have a tooth extracted under the influence of laughing gas, when, in consequence of an unlooked for *contretemps*, the dentist was unable to administer it. The extraction was therefore performed without it, but the operation was rendered almost painless by the writer vividly imagining pleasant ideas, and mentally repeating to himself, "How delightful! how delightful!" Every one will envy Dr. Tuke his powers of self-control and mental abstraction, and not a few will envy him the possession of ideas which were so pleasant as to preponderate over the wrench of a tooth-drawing. The chapter on the influence of the will upon the voluntary muscles is enriched by a consideration of the facts of "thought reading." Two diagrams have been added, but it is extremely doubtful whether they afford any assistance to the reader in understanding the subject matter of the work. The chapters on psychological and physiological principles are the weak portions of the book.

So long as Dr. Tuke confines himself to the records of occurrences, his narrative power, his simple, clear style, and his conscientious accuracy, render his book both pleasant and profitable; but when he deals with principles and with the reasonings of psychology he exhibits that misapprehension of the main issues involved, which almost every medical writer on mental diseases and mental phenomena has up to the present time displayed. According to Dr. Tuke, not only the special sense-organs, but the special senses, and sensation, special and general, belong to the body and not to the mind. The book is however avowedly written for the purpose of supplying a collection of facts, and not for the discussion of psychological principles, and in its main purpose it is unquestionably successful.

ABSTRACTS AND EXTRACTS.

OBSTETRICS.

On the Prevention and Treatment of Puerperal Septicæmia. A paper read by Dr. T. Gaillard Thomas, on December 6th, 1883, before the New York Academy of Medicine.—After urging the necessity of such a paper at the present time, and describing some of the anatomico-pathological conditions of the parturient state, and the early symptoms of an attack of puerperal septicæmia, he alluded to the difficulty of exactly defining puerperal fever. He would not adopt any definition which did not acknowledge the affection to be septicæmia, no matter what form it assumed. He did not consider "metria" any improvement on the old term. On the other hand, "puerperal septicæmia" conveyed a clear and definite idea of the nature of the disease. Personally, he believed that there was a specific poison, although at present it was impossible to state its exact nature; but it could be introduced into the system in only two ways, viz.: through the atmosphere, or by direct contact of the physicians or nurses' fingers or of clothing or bed-covers with the genital tract. In well-regulated lying-in hospitals positive rules for the prevention of puerperal septicæmia existed; in private obstetrical practice a laxity prevailed which was nearly akin to criminality. The parturient woman should be regarded as a patient about to undergo a capital operation. For prophylaxis in private practice he recommended—1. Clearing the room of every unnecessary article, and sprinkling the floor, walls, ceiling, and furniture with a solution of carbolic acid 10 per cent., or of mercuric chloride ·001 per cent.; 2. Scrupulous cleanliness of nurse and physician, and the use of a disinfecting bath if either has been exposed during the previous fourteen days to the poison of scarlatina or any other septic poison. 3. Vaginal injections of mercuric chloride solution or other antiseptic every four hours throughout labour. 4. The hands, and every instrument or utensil used during labour, to be rinsed with a ·001 per cent. solution of mercuric chloride. 5. Efficient production of the third stage, and the administration of ergot in moderate doses three times daily for at least a week. 6. Careful examination of the genital tract at the end of labour by the physician, who should take nothing for granted, and who must suture a ruptured perinæum, and treat any slight solutions of continuity by the application of ferric sulphate and carbolic acid, and flexible collodion. 7. To give, in six or eight hours, a warm antiseptic vaginal injection, and a vaginal suppository containing iodoform gr. 3 to gr. 5: the injections to be repeated every eight hours, and the suppositories every two or three hours, and kept up for at least ten days. 8. If catheterization is needed, to use only a new gum elastic catheter, previously dipped in an antiseptic solution. 9. The physician should convince himself that the nurse has the ability to use suppositories, syringe, and catheter as required. He strongly condemned the use of intra-uterine injections as a prophylactic, except after very severe operations within the uterus. When septicæmia had occurred, he recommended as treatment—1. Morphia *sub cute*, to allay nervous irritability and pain, employing a new needle, which must be thoroughly cleansed after use. 2. Intra-uterine injections of a warm ·0005 per cent. mercuric chloride solution every three or five hours according to circumstances; ergot and ferric sulphate being always at hand in case of the dislodgment of a thrombus. 3. Reduction of temperature—best effected by Townsend's rubber-coil (a mat composed of a long rubber tube coiled in concentric circles upon itself)—which was placed upon the abdomen, extending from the symphysis pubis to the ensiform cartilage, and through which a constant stream of ice-water was passed. By its means a temperature of 104° F. could be reduced to, and maintained at, 100° F. Its prolonged use was essential, and by keeping hot-water bottles applied to the patient's feet no bad results followed its employment. 4. The use of febrifuges—quinine, Warburg's tincture, salicylate of soda. 5. An ample milk diet, with animal broths. 6. Efficient and abundant assistance. If carbolic acid were employed for intra-uterine injection, a 2-per cent. or 2½-per cent. solution was recommended.—A subsequent speaker pointed out the difficulties in carrying out Dr. Thomas's plan of treatment, especially when the patient was in moderate circumstances.

Gangrene of the Abdominal Integument following Puerperal Parametritis.—Dr. M. Thiede, of Lübeck, relates two cases of the above rare kind, in a recent number of the *Zeitschrift für Geburtshülfe und Gynäkologie*. He has not been able to find any previous description of this complication. The first patient, aged 27, delivered of her second child, went on well for eight days. Then she began to have abdominal pain and headache, with sleeplessness and febrile symptoms, and the lochia which were purulent became again sanguineous. The hæmorrhage from the uterus continuing, in spite of general treatment, on the 17th day of the lying-in the interior of the uterus was explored under anæsthesia, some outgrowths from the placental site removed, and the cavity washed out with a carbolic acid solution. From the second day after this treatment the bleeding completely ceased: but febrile symptoms continued, and a firm parametric infiltration developed around the cervix. Signs of cystitis then appeared, and to this was soon added a tender swelling of the integuments on each side along Poupart's ligament. This continued to spread till it reached to within three fingers' breadth of the navel. The swelling was at first hard, then became soft and boggy. On the 23rd day after the operation vesication appeared, then subcutaneous abscesses, and finally the skin sloughed in one piece, leaving a granulating surface reaching from one iliac spine to the other, and to the height already mentioned. Aided by skin grafting, this healed up, and the patient did well. The second patient was aged 25, and had had three children and one miscarriage. A second miscarriage at the third month occurred; and for three days after this the patient went on well. Then came profuse hæmorrhage; and a piece of placenta projecting from the os was removed. This did not stop the bleeding, and therefore, under chloroform, the uterus was explored, the remainder of the placenta removed, and the cavity washed out with carbolic acid. Next day a rigor occurred, and on the 6th day an exudation was to be recognized in the right parametrium, which soon extended behind and to the left of the uterus, and slight cystitis came on. On the 20th day after removal of the placenta, fresh symptoms appeared, severe pain was felt in the lower abdomen, and there was redness, swelling, and tenderness of the skin over the symphysis. In the left inguinal region were inflamed lymphatic vessels. The inflammation spread; vesication, and then gangrene of the skin took place, an ulcer being left measuring about 13 centimetres by 6. There was also suppuration of inguinal glands on both sides. The patient recovered after an illness of about 13 weeks' duration. Dr. Thiede attributes the gangrenous inflammation to septic infection, the skin being predisposed to slough by the pressure and bruising of it necessarily involved in bimanual manipulation of the uterus. We may also mention, points to which Dr. Thiede does not attach much importance, that the patients had been treated, prior to the gangrene, with mercurial inunction, and the application of ice to the hypogastrium. The ice, he says, gave great relief to the pain of the parametritis, so much that when it was removed the patient clamoured for its replacement.

Plaster of Paris Pessaries.—Dr. Lee Read, Professor of Obstetrics and Gynæcology in the Cincinnati College of Medicine and Surgery, describes an improvemens on the method employed by Dr. Dawson, who packed the upper portion of the vagina with absorbent cotton saturated with a mixture of plaster of Paris and water. The main objections to this plan are the persistent pressure necessary to the act of thus packing the vagina; the consequent distortion of the parts, and the liability to cellulitis; and the remarkably short time in which these very absorbent pessaries become fœtid and septic. Dr. Read, therefore, employed a mixture of plaster and water injected from a metallic syringe which was passed into the vagina by the aid of a Sims' speculum, the syringe being gradually withdrawn as its contents were projected. In the bottom of the syringe some dry absorbent cotton was packed, which, being discharged with the plaster, formed an effectual plug, and served the threefold purpose of preventing the escape of the plaster from the vagina, forming a cushioned lower extremity for the plug, and obviating the formation of disagreeable sharp corners. The plaster should remain in the vagina until the secretions have overcome its astringency, when it can be removed without damage to the epithelium; it is then reproduced in rubber, and the vulcanised pessary thus obtained—having a central canal for the escape of secretions—is a satisfactory and valuable instrument. Dr. Reed sometimes treats cases of colpitis with the vaginal plug of plaster of Paris, which is a powerful astringent and an efficient alterant.—*New York Med. Jour.*, Dec. 22, 1883.

Puerperal Diseases.—Dr. Siridey, physician to the Lariboisière Hospital, has just presented to the Académie de Médecine (*Bulletin*, January 22nd) an important work, "Les Maladies Puerpérales," founded on his eleven years' study in his hospital service, into which about 900 women are annually admitted. The opinions held in the work are thus summed up by this author:—1. Essentially puerperal fever has no existence. 2. The diseases of lying-in women are constantly dependent upon two clinical types, which may be distinct or associated, and which correspond to the primary localisation of lesions in the lymphatics or the veins of the uterus. 3. A lying-in woman is simply a patient suffering from a wound, and, as such, is exposed to all the complications of surgical wounds. 4. She does not herself furnish the germs of septicæmia, observation invariably demonstrating the contagion and transmissibility of puerperal diseases, and the infection of their subjects by the mediate or immediate contact of organic substances in a state of putrefaction, &c. 5. Consequently the chief prophylactic indication in puerperal affections consists in placing the lying-in women in the same hygienic conditions as those required in surgical operations.

Ovariotomy in Italy.—Dr. Peruzzi has recently published in the *Raccoglitore Medico* the results of the fourth hundred ovariotomies performed in Italy in the course of eleven months—from June, 1882, to May, 1883. The first hundred occupied eighteen years (1859–77), and the second and third hundred were performed each within two years. The following are the result:—

First hundred,	Recoveries	37,	Deaths	63.
Second „	„	64,	„	36.
Third „	„	74,	„	26.
Fourth „	„	79,	„	21.

Besides the last hundred of the completed ovariotomies, there were also seven incompleted operations, with four recoveries and three deaths.—*Presse Med. Belge*, Jan. 13.

An Antiseptic Post-Partum Pad.—Dr. J. H. Garrigues recommends the following:—After removal of the secundines, the patient is washed with a warm corrosive sublimate solution (1 in 2,000), and a piece of lint 6 inches by 8 inches, folded once, so as to be 3 inches wide, is placed over the vulva; outside this, a piece of oiled muslin 9 inches by 4 inches; over that, a large pad of oakum; and finally the whole is fastened to the binder by a piece of muslin 18 inches square, folded together so as to form a kind of boat, 5 inches wide, and pinned in front and behind at each of its corners. This dressing is renewed four times in the twenty-four hours, and at the same time the genitals are washed with the bichloride solution.—*N. Y. Med. Jour.*, Dec. 29, 1883.

A Plea against Prophylactic Injections after Normal Labour.—Dr. Baruch, under this title, protests, in a paper published in the *New York Medical Journal*, January 5th, against the practice, now becoming prevalent, of employing antiseptic injections after normal labour, for the purpose of prophylaxis. "Sanctioned as it is," he says, "by some of our highest and most justly eminent authorities, the use of prophylactic injections in the puerperal period will surely become a general practice, if the subject be not calmly discussed in the light of experience. If I have aroused attention to the danger which threatens the puerperal woman of the future from this practice, I shall be content. Nothing but a strong sense of duty has prompted me to venture to differ from men whose views I have always regarded with respect, from whom I have learned much in the past, and by whom I expect to be guided largely in the future, when their teachings do not conflict with the results of experience and common prudence."

The Treatment of Ruptured Perinæum by Iodoform.—A recent number of the *Zeitschrift für Geburtshülfe und Gynäkologie* contains an article by Dr. C. Behm, on the above subject. He points out that in the region of the vagina and perinæum the efficient application of the ordinary kinds of antiseptic dressing is very difficult, if not impracticable, on account of the unavoidable fouling of them by urine and fæces. Iodoform has the property of closely adhering to wound surfaces, over which it forms a felt-like covering, difficult of detachment. It is, therefore, peculiarly suited to the needs of the ano-vulvar region. The method which Dr. Behm recommends, is the painting the surface of the wound with "Iodoform-collodium" (Iodoform one part, flexible collodium ten parts). He believes that the protective film thus formed does not act as a foreign body, and prevent primary union, but that, on the contrary, by checking secretion, it favours this mode of healing.

REPORTS OF SOCIETIES.

PATHOLOGICAL SOCIETY OF LONDON.

Tuesday, February 20th, 1884.

J. W. Hulke, Esq., F.R.S., President, in the Chair.

Infantile Paralysis.

Dr. Angel Money read notes and showed microscopic sections of the spinal cord from a recent and an old case of infantile paralysis. The recent case was that of a female child, aged two years, who died sixteen weeks after the onset of paralysis of both legs. The old case was that of a boy, aged seven years, who died of diphtheria five years after the commencement of paralysis of the right leg. The limbs of the recent case were much swollen, but did not pit on pressure; they also felt cold and damp. The right limb of the second case was greatly wasted, and considerably shortened, but had no œdema. The microscopical appearances of the two cases presented some striking differences, but Dr. Money believed they were only different stages in the progress of the same pathological affection. In the centre of the lumbar enlargement of the recent case there was great engorgement of the vessels which, indeed, seemed actually blocked with blood; there was great infiltration of the anterior cornua with leucocytes, and the true nerve-cells could not be discriminated. It was further observed that the disease

was not confined to the anterior cornua, but spread away a little in all directions—the morbid appearances were not sharply bounded, but seemed to have ill-defined outlines. The word "splash" would seem best to indicate what was meant. The old case showed almost complete absence of nerve-cells in the right half of the lumbar enlargement, and the anterior cornu was much wasted, being composed of a rather dense nucleated tissue, which stained deeply. The characters of both the spinal cords described, were such as belonged to the midst of the disease—the changes were less marked the farther one went away from the centre of mischief. Dr. Money next spoke of the pathology of the disease. He believed that the majority of cases were of vascular origin. By which was meant the belief that some damage, not of a permanent character, was done to the walls of the blood vessels; and in Cohnheim's view all the phenomena of inflammation ensued on such mischief. Some cases might commence as a hæmatomyelia, but he rather thought that where hæmorrhage did occur it was but an accompaniment of the inflammation; for, again, Cohnheim had shown that where the vascular damage was great, actual blood extravasation took place. It was also known that Charcot and Bouchard had said that hæmorrhage into the grey matter of the spinal cord was always the result of myelitis; but Dr. Money considered that the hæmorrhage and inflammation were but concomitant phenomena, and the result of a previous common cause.

Dr. SHARKEY thought that the capillaries would be in greater number in the grey matter than in the white, and it was the capillary blood supply which was the most important. Then, according to Rolleston, the central nervous system was least likely to be interfered with in its blood supply. It was well known that in starvation the nerve centres suffered least.

Dr. WILKS thought that these theoretical views should be received with caution, the most active parts, functionally, were the most liable to disease, for this reason hemiplegia was very common, the lumbar and cervical enlargements were most actively in use and most liable to disease. The doctrine was not in accord with the views he had always held and taught.

Mr. R. W. PARKER asked how the disease was produced, the spinal cord was so well protected, *e.g.*, from the heat of the sun, and many cases occurred in cold weather. Then, what caused the disease at a particular spot? Many cases, indeed, affected at first a large area of the cord. He would agree that it was a change about the large cells rather than in them.

Dr. CARRINGTON, in regard to the vascular supply of the cord, had found that the blood supply was not nearly so regular or good as was described in books.

Dr. MONEY said that his drawing was very diagrammatic, but his point had been that the grey matter was farthest off from the supply of blood. In regard to the spinal cord being so well guarded, he referred to Moxon's views, and also alluded to the length of the anterior and posterior arteries, it was the pressure rather than the supply that was at fault. He had no reason to explain why one part of the cord more than another should be affected.

Amyotrophic Lateral Sclerosis.

Dr. COXWELL described this case. The patient was a woman, who first lost power in one thumb, then the limbs gradually became affected, and lastly speech. When she came under observation, eighteen months after the onset, she could not stand alone, the faradaic excitability of the muscles of arms and legs was much diminished. She died, with the usual symptoms of bulbar paralysis. At the *post mortem* the cord was atrophied, the crossed pyramidal tract stained deeply, so did the column of Türck. The nerve tubules were much diminished in the lateral columns. In the cervical and dorsal regions multipolar cells were wasted or absent, the grey matter was in places unusually vascular. In the medulla similar changes were found, the nucleus of the hypoglossal nerve being distinctly affected. The case closely agreed with Charcot's description, but the rigidity was less marked, and the onset was unusually definite.

Dr. ORMEROD thought that the order of events was very important; at first there was wasting, but no symptom of lateral sclerosis for some time. It was usually held that the reverse took place, and that the sclerosis commenced in the lateral columns, and spread thence to the grey matter. The case was one of a combined systematic sclerosis.

Dr. BEEVOR referred to a case he had already published in *Brain*—atrophy of hands, bulbar paralysis, then stiffness of the limbs, was the order of events in his case.

Dr. COXWELL referred to the difficulty of deciding where the disease commenced.

Malignant Disease of the Mesentery.

Dr. SAINSBURY described this case. The patient complained of weakness and loss of flesh; then anæmia was noticed, and a tumour in the hypogastrium. There was some fever not explained by the physical signs; later on there was abdominal pain and tenderness, and he died of peritonitis. A large mass was found in the hypogastrium, containing a large cavity, which had ruptured into the peritonæum. It seemed to be confined to the mesentery, and the other viscera were healthy. It was impossible to determine whether it had originated in a gland or not. He referred to a similar case, recorded in the Transactions, vol. xx, by Mr. Arnott, and one by Mr. Callender, in vol. xv. He noted that the tumour was almost confined to the mesentery, and that it had probably undergone necrosis in its centre, and had thus become hollowed out. He discussed the clinical symptoms at some length, and especially the movable nature of the tumour, the cachexia, and the pyrexia to which he had already called attention. The tumour was a round-celled sarcoma.

Mr. DORAN asked as to the presence of ascites. He had found no definite relation between malignant disease of the omentum and ascites, in a somewhat large experience. He asked whether there was any pleurisy in this case.

Dr. SAINSBURY said that no ascites had been recognised during life; the peritonitis was quite recent. There was only an old patch of pleuritis.

Malignant Disease of the Peritonæum.

Dr. HOBSON described the case of a woman who had a large accumulation of fluid in the peritonæum, and was tapped several times; nodular masses could be felt after the tapping. The disease was first recognised after her delivery. She died two months later. At the autopsy the peritonæum was universally adherent, and a multilocular cystic growth was found. Microscopically, the growth did not seem to conform to any of the ordinary types, as the cells were of varied shapes. This case closely resembled one described by Mr. Knowsley Thornton in the Society's Transactions.

Mr. DORAN said that occasionally large multilocular cysts ruptured, setting up small tumours which repeated the character of the original tumour. In a less malignant form, often small growths were secondarily deposited, but without doing much harm.

Two cases of Purpura Hæmorrhagica, in which Bacilli were present.

Mr. WATSON CHEYNE showed some sections from fatal cases of purpura hæmorrhagica. Dr. Russell's case was that of a girl, aged twelve years, who died of purpura; at the *post mortem*, the spleen was not much enlarged; on examining the heart, he found sub-exocardial hæmorrhages, with the capillaries, blocked by plugs of masses of bacilli, some of which contained spores; they had no peculiarities. They had evidently been growing for some time. Dr. Pye Smith's

case was a boy, aged fourteen, who had never bled before. He had ailed ten days, bleeding from gums and nose. Purpuric spots appeared. The hæmorrhage ceased, but he died from anæmia. Ecchymoses of nearly all his membranes, and hæmorrhages in the brain, lungs, tonsil, and testicles were found. On examining the lungs near the hæmorrhages, the vessels were found completely blocked with plugs of organisms, *i.e.*, micrococci forming long chains, they stained well with methylene blue. There were none in the other vessels. In one tonsil, deep down, he found some vessels plugged, but not in the heart, of which, however, only a superficial portion was examined. He concluded that these cases of purpura were associated with bacilli, which plugged the vessels leading to hæmorrhages, the organisms were different in the two cases, he could not explain this. He suggested that the primary affection resulted in such an altered condition of the fluids of the body, that some of the many organisms present in the mouth and alimentary canal, might be able to penetrate into and live in the blood, and thus form emboli.

Dr. PYE-SMITH said his case was a very typical one of purpura hæmorrhagica, there was no doubt that the organisms were micrococci in this case. In purpura mechanical lesions often caused fresh hæmorrhages. The blood was examined during life, but not for micro-organisms.

Dr. MONEY had examined the blood in two cases, and had not succeeded in finding any micro-organism.

Dr. STEPHEN MACKENZIE said it would be hasty to assume that organisms would always be found on the strength of these two cases. He referred to iodic purpura, which could not be attributed to an organism, owing to the rapidity with which the purpura came on. He said this without wishing in the least to disparage the work of Mr. Watson Cheyne.

Mr. BARWELL made a few brief remarks.

Mr. CHEYNE, in reply, said that the examination of the blood was not likely to lead to anything. This enquiry was, he thought, more difficult than that of any of the other forms of bacilli.

Living Specimen.

Mr. DENT showed a woman, aged 57, who had suffered from perforating ulcers of each foot.

Card Specimens.

The PRESIDENT.—Two drawings of cases of cancer of the breast.

Mr. SHATTOCK.—A cast of a double vena cava, the left being the larger.

OBSTETRICAL SOCIETY OF LONDON.

WEDNESDAY, FEBRUARY 6TH, 1884.

DR. GERVIS, President, in the Chair.

Auvard's "Nest."

DR. MATTHEWS DUNCAN exhibited the "nest" or "incubator" of Dr. Auvard. A similar machine had been used for some years in the Paris Maternité by Dr. Tarnier, but upon this Dr. Auvard's was an improvement. It was planned to maintain a uniform temperature. It was simple, cheap, and useful. Dr. Auvard stated that by its use, the mortality of children under 2,000 grammes weight at birth had been reduced from 65 per cent. to 38 per cent. The child was placed in it clothed. The machine was kept warm by hot-water bottles, the air moistened by passing over damp sponges, and ventilation kept up and watched by a little anemometer. Any ordinary nurse could easily manage the whole matter.

Dr. FANCOURT BARNES had seen a similar machine in use at the Hôpital Tenon. He believed that Dr. Tarnier, not Dr. Auvard, was its originator.

Hearson's Incubator.

Dr. GODSON exhibited Hearson's incubator, and introduced its inventor, who explained it.

Monstrosity.

Dr. HORROCKS exhibited this specimen, which belonged either to the order exencephaliens or pseudencephaliens; it was not possible, until it had been dissected, to say which.

Uterus removed per Vaginam.

Dr. W. A. DUNCAN exhibited an entire uterus with epithelioma of the cervix, successfully removed per vaginam, by Schröder's operation.

New Cephalotribe.

Dr. FANCOURT BARNES exhibited a new cephalotribe he had had made. It was long, with a French lock, the perinæal curve, and Aveling's handle-curve. It allowed traction to be made in the brim of the pelvis.

The PRESIDENT was accustomed to use Hicks's cephalotribe.

Dr. ROBERT BARNES had put this instrument to a practical test, having used it in a case of contracted pelvis, in which he had failed to deliver both with his own forceps and with Tarnier's. It worked admirably, and he thought it might be stamped *probatum est.*

The business of the annual meeting was then proceeded with. The list of officers proposed by the Council was accepted by the Society, and the President delivered an address.

HARVEIAN SOCIETY OF LONDON.

THURSDAY, FEBRUARY 8TH, 1884.

GEORGE P. FIELD, M.R.C.S., President, in the Chair.

UPON taking the Chair for the first time as President, Mr. GEORGE P. FIELD addressed a few words to the meeting, congratulating the Society not only on its successful career in the past, but on its present prosperity, shown by the number of its members and the sustained fulness of its meetings, and especially on the promise of its increasing usefulness in the future, of which no better proof could be given than the titles of the papers to be read at the ensuing meetings during the session. For much of this success the Society was indebted to the untiring zeal of the hon. Secretaries, Dr. W. H. Lamb, whose labours had just come to an end, and Mr. J. Ernest Lane.

Sub-periosteal Hæmorrhage in Infantile Scurvy.

Mr. EDMUND OWEN recorded a case of Infantile Scurvy, the patient, a girl of twenty months, having recently been under his care at St. Mary's Hospital. She was anæmic and of leaden hue, and lay moaning in bed; her right lower extremity was immensely swollen from sub-periosteal hæmorrhage around the femur; the skin was white, tense, œdematous, and glistening, it was never reddened or hot. The gums were swollen, spongy and bleeding; the ribs were beaded, and the radii enlarged at the carpal end. The mother had died of phthisis, and the infant had been brought up on condensed milk and the various patent foods—a typical scurvy diet—with none of that valuable anti-scorbutic, fresh cow's milk. The treatment comprised warmth, cod-liver oil inunctions, fresh cow's milk and water, and the sweetened juice of fresh oranges, and vegetables, together with elevation and compression of the limb. The surface of the femur, explored with a fine canula and trocar, was found extensively stripped of its periosteum, but there was no suppuration. At once the

patient began to improve, and in four weeks its convalescence was completely established, the effused blood being entirely absorbed. Mr. OWEN expressed surprise at such cases being so rarely recorded in London, where many hand-fed children subsisted on a scurvy diet. Possibly some genuine cases of infantile scurvy were overlooked by the practitioner, because the gums did not happen to be spongy; or again, as had been suggested by Dr. Cheadle, the scorbutic origin of certain spongy gums might not be recognised because the other signs of scurvy were absent. The characteristic symptoms of scurvy did not always go hand-in-hand. He concluded with a strongly adverse criticism of the general employment of condensed milk, and of the speciously advertised artificial foods, without any adequate supply of fresh milk; often infants refused cow's milk because it was not sufficiently diluted.

Dr. BUZZARD, from his experience of scurvy in the Crimean war, expressed the opinion that association with rickets was by no means necessary for the production of such a condition as that described by Mr. Owen. He had seen many instances of periosteal hæmorrhage occurring along the front of the tibia for example, and on the inferior maxilla in men suffering from scurvy alone. Nothing could be more important than the observations of Dr. Barlow, Dr. Cheadle, and others, upon the condition found in improperly fed children. Although usual, sponginess of the gums was no necessary symptom of scurvy; he thought it might be absent in about twenty per cent. of the cases, even when the other features were very strongly marked. Another diagnostic point of great importance was the presence of ecchymoses, often overlooked or attributed to accidental bruises. The recognition and appropriate treatment of a scorbutic affection rescued a patient from grave peril, and ensured a recovery remarkably rapid and complete.

Dr. CHEADLE stated that he had studied the disease in seven children, his observations having being the first to draw attention to the subject. He attributed the malady to the use of artificial foods, which lack the fresh vegetable quality, and are generally deficient in nitrogen. This evil should be met, in cases where cow's milk is not tolerated, by raw meat, meat juice and potato-mash. He had, however, seen a case of infantile scurvy, recover completely under the exclusive use of Swiss milk. He endorsed Dr. Buzzard's remarks concerning spongy gums, but in his experience bruises were not often observed.

Dr. SYMES THOMPSON alluded to the causation of pulmonary hæmorrhage from a scorbutic tendency, and gave an instance in point.

Mr. JOHN MORGAN pointed out that the sub-periosteal hæmorrhage showed no tendency to suppuration in scurvy, and submitted that the hæmorrhagic affections might involve the medullary cavity of bone as well as the surface.

Mr. PEPPER suggested that effusions of blood, such as those displayed in the specimens exhibited, were not infrequently the artificial result of injections performed after death. It should be borne in mind in diagnosing rickets, that beading of the ribs might be physiological.

In his reply, Mr. OWEN stated that he had failed to discover in rickets that tenderness of the bones which Sir William Jenner had described.

Deformities of the Fingers and Toes.

In an interesting paper Mr. NOBLE SMITH reviewed the following subjects:—(1.) Congenital hypertrophy of fingers and toes. (2.) Deficiencies of digits. (3.) Rudimentary digits. (4.) Intra-uterine amputations, &c., by the pressure of the umbilical cord, or of fine membranous bands. (5.) Budding of digits at the extremity of a stump. (6.) Double-hand. (7.) Supernumerary digits. (8.) Cleft thumb. (9.) Union of fingers at tips. (10.) Web formations. (11.) Permanent contraction of fingers. The ætiology and the surgical treatment of many of these conditions were discussed in the paper, and illustrative drawings were circulated.

In the ensuing discussion, Dr. THOMPSON and Mr. PEPPER referred to the subject of maternal impressions, and after Mr. NOBLE SMITH'S reply the meeting was adjourned.

GENERAL CORRESPONDENCE.

THE DEBATE ON CHOLERA.

[To the Editor of the Medical Times.]

SIR,—In the leading article, on "The Debates on Cholera at the Epidemiological Society," in the *Medical Times and Gazette* of 16th instant, the following occurs:—

"Setting aside the opinions of such extreme partisans as Inspector-General Lawson, who, as our readers may remember, ignoring entirely the results of recent microzoic pathology, denied in a communication to our pages, last July, that there was any evidence of the existence of a material entity passing from one individual to another in small-pox or scarlatina (though he did not reply to our question as to vaccination!) we may venture to express our belief that the dispute is, as regards most, a battle of words."

This serious accusation is, on the part of the writer, verily something more than "a battle of words," for every allegation in it is groundless. My letters appeared in the numbers for the 4th and 11th August (not July); neither small-pox nor scarlatina was even incidentally alluded to in them; and the question as to vaccination, which it is insinuated I was so much to blame for not answering, is not to be found among the comments appended by the Editor to my first letter. The part played by microzoic organisms in the production of cholera has yet to be determined, and, until this be so, any view adopted regarding their operation is but an assumption, and forms a very unsafe basis for further generalisation.

I leave it for the readers of the *Medical Times and Gazette* to consider how far they can place confidence in the judgment and dicta of a critic, who allows himself to form and to emit opinions for their guidance, so completely at variance with facts.

I am, Sir, &c.,
ROBT. LAWSON,
Inspector-General.

London, February 18th, 1884.

[If in our article, hastily written during the night following the adjourned debate at the Epidemiological Society, we did not fairly represent Inspector-General Lawson's personal views, we owe him an apology, and must express our satisfaction at finding that he is not so extreme a partisan as we thought him; but when a man takes up arms in defence of a friend's opinions, he cannot complain if he is supposed to hold the same, or if an opponent writing from memory, identifies the two. If Mr. Lawson will refer back, as we have since done, he will find that the controversy began on July 21st, when we criticised Surgeon-General Cuningham's paper, in a leader entitled "Credulity, Scepticism and Agnosticism in Science," and he will see that we there denied as strongly as he could wish that cholera and enteric are contagious in the same sense as small-pox and scarlatina. Yet it was this article that called forth his protest in the August numbers, and this it was that contained the appeal to vaccination, and the challenge, also unanswered, to Dr. Cuningham to drink, if he dared, cholera stools. We still maintain that the language used by Dr. Cuningham perfectly justified our criticisms, severe though they may have been. We could fill two pages with extracts to our purpose, but must content ourselves with a few. In p. 60, col. 2 (July 21st), Dr. Cuningham says [the italics are ours], "Germs are supposed to account not only for cholera, *small-pox* and *enteric fever*, but also for *tubercle* and ordinary malarial fever . . . . but, as a matter of fact, do these germs really exist? Have they been found in diseases such as small-pox . . . . Is there a single organism derived from a person suffering from a particular disease which can be said to be the cause and not the consequence of that disease? Is there a single organism found in disease which alone is capable of producing that disease?" He here places small-pox between

cholera and enteric fever, which we do not, while to each of the questions that follow we answer unhesitatingly—Yes. It was in small-pox and cow-pox that such germs were first recognised by Chauveau and Sanderson, and found capable of reproducing the disease when separated from the pus-cells and clear albuminous fluid. And whether or not Spina has found other bacilli indistinguishable from those of tubercle, microscopically and chemically, matters little, though Dr. Cuningham urges it as disproving the specificity of the latter, for this has been placed beyond question by the experiments of Mr. Watson Cheyne, who, with invariable success, produced tubercle in the eyes of rabbits by the inoculation of the special bacillus, after hundreds of cultivations in gelatine. It was these researches in particular which we considered had been ignored by Dr. Cuningham. Dr. Cuningham (page 61, col. 2) says, "I venture to think that there is very little to support the theory, that either cholera *or enteric fever* is due to a specific poison. . . . . You will ask, then, what can be the cause or causes of this *and other diseases?*"—and he goes on to explain them by *forces* rather than by *entities*. "The doctrines," he says, "which have been so commonly preached of late regarding germs, and the danger arising from the sick, have been attended with most disastrous consequences, and there seems every reason to fear that *these disastrous consequences may increase* rather than diminish. Much domestic misery is caused by the removal of a sick person from the midst of his family . . . . . to die in a hospital, unattended by those whose duty, under any circumstances, was to have nursed them in their extremity." Surely, if these earnest warnings have any meaning, they are directed against the notification of infectious diseases, and the establishment of special hospitals for small-pox and fevers generally, and are not intended to refer to cholera alone, if, indeed, at all. With Dr. Cuningham's paper before us we cannot retract a word we have written; the head and front of our offending is that, when Mr. Lawson came forward as the avowed champion of "his friend Dr. Cuningham," we assumed that he held the same views, and after the lapse of six months thought only of the foeman with whom we had actually exchanged blows.

We do not write without any practical acquaintance with our subject, having worked in the midst of cholera albeit in London only; our views on the subject of its ætiology and communicability may have acquired greater precision by study, but are essentially unchanged, and we would invite friendly criticism of them as set forth in our articles on "The Propagation and Prevention of Cholera;" "Credulity, Scepticism, and Agnosticism in Science;" "Dr. Hunter in Egypt," last year; and that on "The Adjourned Debates" in this.

THE WRITER OF THE ARTICLES IN QUESTION.]

P.S.—Unfortunately the postal pressure of St. Valentine precluded proper correction of the last article, in which, besides inaccurate punctuation, which mars the sense in some places, two errors occurring in one sentence, "specialty" for "specificity," and "to be" for "to beg the question," may lead to misapprehension of our meaning.

AMENORRHŒA AND VICARIOUS MENSTRUATION.

[To the Editor of the Medical Times.]

SIR,—I have little to object to in Dr. Bantock's criticisms of my letter on Amenorrhœa and Vicarious Menstruation, seeing that this gentleman's opinion accords in the main with my own; but I feel bound to reply to his expression of surprise at my statement, that amenorrhœa is still treated as a substantive complaint by gynæcologists. I said this advisedly, and will explain my meaning by examples lately under my notice:—that of a young lady with chlorosis, who is taking permanganate of potash because she is informed it has a very special power over the uterus; the case of a lady who is having some instrument applied internally, this being a method of stimulating the uterus, as I am informed, recommended by the late Sir J. Simpson; and thirdly, the case of a young lady, the subject of numerous troubles, amongst which amenorrhœa takes a very prominent place in her mother's eyes, who has her under the care of a well-known gynæcologist, and had a galvanic current assiduously passed through the lower regions of the body for several months, I need scarcely add, without any effect. Of course, I do not allude to the action of mothers who so frequently take their chlorotic daughters to specialists.

Your obedient servant,
SAMUEL WILKS.

Grosvenor Street,
February 16th, 1884.

VICARIOUS MENSTRUATION.

[To the Editor of the Medical Times.]

SIR,—I think with such a mass of evidence as that presented in section 1,143, 2 and 3 of the *Medical Digest*, together with an equal number of cases that have been since recorded, which will appear in the "Appendix," no one can doubt that there is some connection between the appearance of blood in different parts of the body and the menstrual crisis.

Yours obediently,
RICHD. HEALE, M.D. Lond.

60, *Boundary Road, South Hampstead, N.W.*
February 20th, 1884.

NEW INVENTIONS & IMPROVEMENTS.

THE WYETH HYPODERMIC CASE.

THE Wyeth compressed hypodermic tablets, introduced into this country by Messrs. Burroughs, Wellcome & Co. of 7, Snow Hill, E.C., have been so favourably received, and are so widely used by the profession, that we need only refer in brief terms to the hypodermic case recently introduced by the same firm. It contains a hypodermic syringe with two needles and sixteen small tubes, holding as many different kinds of hypodermic tablets,

forming a very complete therapeutic armamentarium. The tubes are retained in their places by little springs, which act very effectively. The case before us contains tablets of sulphate and bimeconate of morphia in different doses, atropia singly, and combined with morphia, each in two different doses, and tablets of strychnine, apomorphia, perchloride of mercury, digitalin, pilocarpin and aconitia. The hypodermic method of drug exhibition has two great advantages over other modes of administration. In the first place, it involves a certain amount of trouble and ceremony, and is not likely to be lightly adopted, or without some definite therapeutic end in view; and in the second place, it renders polypharmacy, or at any

rate simultaneous polypharmacy, impossible. The hypodermic syringe bears to the medicine phial somewhat the same relation that the consultant bears to the general practitioner—it is only to be used when there is something serious the matter.

PINE EXTRACT (FOR BATHS).

Under the name of "Pine Extract," Messrs. Christy and Co., of 155, Fenchurch Street, E.C., have introduced a preparation of the active principles of the pine, made from the fresh needles, which has been widely used as an addition to baths at Homburg, Grund, and other German watering-places. There can be no doubt as to the stimulating influence which the oleo-resins of the pine family exert, in a concentrated form, upon the skin, and in an extremely diluted form upon the mucous membranes. The idea of applying them in a diluted form to the skin, not with any definite object, as to cure a patch of eczema or psoriasis, but with the view of exerting a mild stimulation on the whole surface of that important and sensitive organ, is by no means a new one. Tar-water was a well known and much lauded specific in the last century, and a decoction made from fir tops is a domestic remedy in France, widely used both for external application and for inhalation. For infants, with their sensitive skins, Christy's Pine Extract, used in the daily bath, provides a perfectly safe means of general stimulation, difficult to obtain in other ways; and it would be worth trying in the case of adults, in whom there is a want of tone in the skin, and an undue tendency to perspire. It certainly provides a more rational means of treating such functional disturbance, if it is to be treated, than the exhibition of internal or hypodermic remedies.

MEDICAL NEWS.

Apothecaries' Hall.—The following gentlemen passed their examination in the Science and Practice of Medicine, and received a Certificate to Practise, on Thursday, February 14th, 1884:—

Hall, William Geo., Swindon, Wilts.
Hill, Geo. Wm., Sydney-street, South Kensington, S.W.
Livermore, Wm. Leppingwell, Queen's-road, Finsbury-park, N.
Martin, Thos. Berkeley, Hylton-road, Sunderland.
Nicholson, Henry Gilbert, St. Peter's-square, Hereford.
Waters, Avery Clough, Mornington-road, Bow, E.

The following gentleman also, on the same day passed the Primary Professional Examination:—

Thomas, Edwin Clifton, of the London Hospital.

Army Medical Department.—List of Candidates who were successful for appointments as Surgeons in Her Majesty's British Medical Service at the competitive examination in London, on February 4th, 1884. The marks shown are those which were gained in order of merit:—J. R. Barefoot, 2,440; R. H. Clement, 2,420; G. D. Hunter, 2,335; W. C. Beevor, 2,300; L. E. Anderson, 2,275; G. B. Russell, 2,250; A. E. C. Spence, 2,220; J. R. Mallins, 2,200; R. J. McCormack, 2,180; H. N. Thompson, 2,169; J. I. P. Doyle, 2,145; N. Manders, 2,120; L. R. Colledge, 2,100; S. F. Freyer, 2,075; C. Birt, 2,070; R. S. F. Henderson, 2,020; H. Mitchell, 2,000; S. Butterworth, 1,990; C. J. Holmes, 1,930; J. R. Lane, 1,920.

Naval Medical Department.—At the competition for Commissioners in the Medical Service of the Royal Navy, held on the 4th February and following days, in the Hall of the University of London, Burlington-gardens, the undermentioned gentlemen were the successful candidates. The marks shown are those which were gained in order of merit:—F. M. Puddicombe, 2,425; D. S. Gunn, 2,230; H. J. Gordon, 2,220; H. Harris, 2,200; E. Corcoran, 2,145; Thomas J. Lloyd, 2,145; J. L. Smith, 2,140; J. H. Thomas, 2,130; F. J. Lilly, 2,120; J. Dowson, 2,070; G. F. Dean, 2,055; G. Welch, 2,050; H. F. Iliewicz, 2,030.

The Indian Medical Service.—The following candidates were successful at the recent competitive examination. The marks shown are those which were gained in order of merit:—J. H. T. Walsh, 2,564; H. Hendley, 2,110; H. E. Banatvala, 2,102; G. H. Fink, 2,071; W. G. P. Alpin, 2,040. There were twenty-one candidates for the five appointments, and all were reported qualified.

Lady Medical Students.—At the present time there are 45 lady medical students in Paris, the great majority of whom are Sclavs. At Liège the number has increased this year from five to 26. In Switzerland there are 68—viz., seven at Geneva, 33 at Zürich, and 28 at Bern; none studying at the Basle Faculty. Pretty well received in France, and thought but little of in Switzerland, lady medical students at St. Petersburg, if not actually imprisoned, are compelled to board in a kind of barrack, under the superintendence of the authorities; so that it is not surprising that whenever they can, these medical aspirants resort to Paris, where they meet with a more liberal hospitality.—*Gazette Méd.*, February 16th.

The Medical Times and Gazette.—Our courteous contemporary the *Boston Medical and Surgical Journal*, thus appreciates the new stage in our progress which we have lately entered upon. "The *Medical Times and Gazette* comes to us in its first issue for 1884, in an enlarged and much improved form. Its table of contents indicates a high order of excellence, and in general this periodical is evidently to become, if it is not so now, one of the most useful of the English medical publications."

Improved Sanitary State of Rome.—Professor Scalzi, a member of the Superior Council of Health, in his report to the Academy of Medicine at Rome, states that while from 1871 to 1880, in a population of 270,495, the mortality was only 5,798 (21·43 per 1,000). During the same period 1861–70, it amounted to 5,785, in a population of 207,956, or 27·81 per 1,000. Thus, during the later decade, there has been a mortality lower by 6·38 per 1,000, than during the preceding ten years.

Society for Relief of Widows and Orphans of Medical Men.—An extraordinary Court of Directors of the Society was held on January 23rd, to receive the resignation of Sir George Burrows, Bart., President (Sir Henry Pitman, V.P., in the chair). Mr. Charles Hawkins, V.P., moved, and Dr. Quain, Treasurer, seconded, the following resolution: "The Court of Directors, in accepting the resignation of Sir George Burrows as President of the Society, desire to place on record its high appreciation and grateful sense of the valuable services he has rendered in this capacity. The constant watchful and benevolent interest which, for seventeen years as President, he has taken in the affairs of the Society has in a great measure contributed to its successful management and its present prosperous condition, and this Court feels confident that Sir George Burrows, on retiring from the office of President, will carry with him the affectionate regard of the entire Court of Directors, and the esteem and gratitude of every member of the Society." Mr. Charles Hawkins moved, and Dr. Quain seconded, "That Sir James Paget, Bart., be nominated as President in the place of Sir George Burrows, Bart., resigned, and that an extraordinary general meeting be called for Friday, February 8th." In accordance with the above resolution, an extraordinary general meeting of the Society was held on Friday, February 8th, Dr. Harvey Owen, V.P., in the chair, and Sir James Paget, Bart., was unanimously elected President of the Society. The members present adopted the resolution carried at the extraordinary Court of Directors, on the resignation of Sir George Burrows, Bart., and requested the Secretary to forward a copy of it to the late President.

International Health Exhibition.—Preparations for the holding of this exhibition are proceeding rapidly. The general committee now numbers nearly 400 members, and from these seventeen sub-committees have been formed. These have all been doing valuable work in advising the executive council as to the nature of objects which it is desirable should be fully illustrated, in obtaining the co-operation of many persons of eminence in the various branches on which the exhibition will treat, and in super-

vising the applications for space. The allotment of space, which has been largely applied for, is being rapidly proceeded with, and applicants will soon be informed of the decision of the executive council with regard to their applications. In response to a request made by His Royal Highness the Prince of Wales, president of the exhibition, the eight Water Companies of London have resolved to exhibit, in a pavilion which is being erected for them, their appliances for the supply, filtration, &c., of water, together with diagrams showing the various processes and localities; and a powerful sub-committee, under the active chairmanship of Colonel Sir Francis Bolton, has been formed to carry out this branch of the exhibition. It is impossible, as yet, to give any definite information with regard to foreign countries; but, so far as we can judge at present, Belgium, China, and India will be the best represented. A Royal Commission has been appointed in Belgium, and the Consul-General in London is their active representative here. To China has been allotted the space which it occupied last year at the Fisheries Exhibition, and a Chinese Tea Garden, Restaurant and Shop will not be the least interesting objects in the exhibition. India is to be adjacent to China, and strenuous exertions are being made to secure the united action of many of the principal tea planters in India, so as to insure a good and representative show of the Indian tea-growing industry.

The Operations in the Red Sea.—It has been decided that the strong detachment of the Army Hospital Corps, which has been ordered to Egypt, will proceed direct to Suakim. It had been previously arranged that the detachment would go to Cairo in relief of the company of the corps already *en route* from there to the scene of operations. Immediately on receipt of the news of Baker Pasha's defeat, Surgeon-General J. Irvine ordered a detachment of medical officers to Suakim, and, with those now *en route* and in readiness to proceed, the medical force at that place will suffice for any emergency. General Stephenson has expressed to Dr. Irvine his approval of the promptness of action of the medical department of the army of occupation in Egypt.

East London Nursing Society.—The annual meeting of this Society was held on Monday. The report mentioned that Princess Christian had consented to become president of the institution. During the year the Society had added two districts to its list, making a total of fifteen parishes worked by the Society. The total receipts for the past year amounted to 1,183*l.* 11*s.* 9*d.*, and the expenditure to 961*l.* 15*s.* 11*d.* The number of cases attended by the Society's nurses was 2,060, and the number of visits paid to patients 43,137.

Navy Medical Service.—The following gentlemen have been appointed surgeons of Her Majesty's Fleet:—Messrs. Francis M. Puddicombe, Donald S. Gunn, Henry J. Gordon, Henry Harries, Edmund Corcoran, John L. Thomas, James L. Smith, M.B., John H. Thomas, Frederick J. Lilly, John Dowson, George F. Dean, M.B., George Welch, and Henry F. Iliewicz.

Nursing in the Navy.—The Lords of the Admiralty have decided to abolish the present staff of hospital nurses, and to replace them by men chosen from the Fleet, who are to receive special training at the hospitals. They will thence be drafted to sea; but, on paying off, will return to their hospitals instead of being sent to the depôt ships as at present.

Contagious Diseases at Aldershot.—The sanitary officer at Aldershot, Deputy-Surgeon-General Thompson, reports that since the suspension of the restrictions imposed by the Contagious Diseases Acts in May last, the influx of vagrant prostitutes has immensely increased, bringing in their train, infection, disease, and dirt, and many other unsanitary influences, thus, no doubt, affecting the health of the troops in the vicinity. The admissions to the military hospitals had increased 50 per cent., while the admissions to the Lock Hospital were nil; the fact is, that women will not now go to this institution until their cases are hopeless. The number of prostitutes had increased twenty per cent.

Deaths from Eating Tinned Meat.—Two boys, residing at Glasgow, died suddenly last week after partaking of a portion of tinned mutton. A surgeon who was called after the death of the boy Webster, certified that he had died from the effects of poison. From enquiry subsequently instituted, it was ascertained that twelve or fifteen persons had been supplied from the same tin, and that in each case sickness, accompanied by vomiting and purging, had followed on partaking of the meat. The body of the boy Miller is to be exhumed, and the police are enquiring into the case.

M. Pasteur.—The National Society for the Encouragement of Agriculture, at the fifth anniversary banquet on Friday last, presented its annual Cup of Honour to M. Pasteur. In returning thanks, M. Pasteur said he was not insensible to praise, but yet praise troubled him, because it belonged to the things of yesterday, and true science always looked forward to new achievements. "There is a great field still to explore," he added. "How many plagues and diseases are there yet to subdue! But have confidence; new methods are discovered, and methods are the soul of science. The great fact evidenced by our meeting here to-night is, the alliance between science and practice. You were the first to believe in the triumph of the experimental method. You have enabled me to carry into the domain of fact, what formerly would have remained in the region of hypothesis. Your farms have been, so to say, branch establishments to my laboratory. The faith which animated me you have shared, and you have largely contributed to help me to add to the wealth of France, which has abundantly requited me."

Lectures at the Royal College of Surgeons.—Prof. Flower will commence his course of nine lectures on the principal types of the human species, in the Theatre of the Royal College of Surgeons, on Monday next, the 25th instant, at four o'clock. The following is the programme of the course, which will conclude on Friday, March 14th:—Introduction: Anthropology and Ethnology; Physical or Zoological Anthropology; Nature and extent of the differences between the permanent types or races of Men, illustrated by comparison between the European and the Tasmanian native; Methods of estimating the differential characters of the various modifications of the human species,—Elements of Craniometry; Characteristics of the Black, or frizzly-haired races, in their typical and modified forms; Characteristics of the Yellow, or so-called Mongolian races; Characteristics of the White, or so-called Caucasian races; Races not readily grouped under either of the above principal types; Classification of the races of the human species.

The Chemical Lung.—On Thursday next, at the Parkes Museum, Dr. Richard Neale will explain the theory and action of the chemical lung adapted to sick-rooms, infectious wards, and other places. Dr. B. W. Richardson will take the chair at 8 p.m.

Royal Institution.—Professor Tyndall will begin a course of six lectures on "The Older Electricity; its Phenomena and Investigators," on Thursday next (February 28th), illustrated by experiments; and Captain Abney, R.E., will begin a course of six lectures on "Photographic Action, considered as the Work of Radiation," on Saturday (March 1st). Professor Hughes will give a discourse on Friday evening next, on "Theory of Magnetism," illustrated by experiments.

Poor-Law Medical Officers' Association.—At a meeting of the Council of the Poor-Law Medical Officers' Association, held at their rooms, 3, Bolt Court, on the 19th of February, it was resolved that a memorial should be addressed to the President and Fellows of the Royal College of Physicians, the President and Council of the Royal College of Surgeons, and the Master and Wardens of the Society of Apothecaries, praying that they will severally memorialise Her Majesty's Government in favour of an amendment of the Poor-Law Medical Officers' Superannuation Act, whereby its present permissive clauses may be made compulsory.

Royal College of Surgeons of England.—At a meeting of the Board of Examiners in Dental Surgery on

the 18th, 19th; and 20th inst., the following gentlemen, having passed the required examination, were admitted Licentiates in Dental Surgery, viz. :—Messrs. Herbert Apperly, Stroud, Gloucestershire ; A. W. Percy Ayres, Stratford Place, N.W.; S. Charles Buckland, Wimbledon Park ; A. Makinson Fox, Teddington ; Harry Baldwin, Moore Street, S.W. ; Stephen Mundell, Castley, near Leeds ; R. Denison Pedley, member 18th July, 1883, Railway Approach, London Bridge.

The City Dispensary.—The ninty-fifth annual festival was held on Tuesday evening, at the Albion Tavern, the Lord Mayor presiding. At the close of the evening, donations to the amount of 380*l.* 7*s.* were announced.

Edinburgh University Tercentenary.—The following programme has been issued of the ceremonies by which the close of the 300th session of the Edinburgh University will be celebrated. The festival is to extend over Wednesday, Thursday, and Friday, 16th, 17th, and 18th of April. It is proposed that on Tuesday evening a grand reception shall be given by the magistrates and council in the Museum of Science and Art. On Wednesday the new College Buildings will be formally opened, and it is understood that the Senatus are endeavouring to get a member of the Royal family to undertake this duty. The proceedings on this day will begin with a reception by the Senatus in their hall, then there will be a religious service in St. Giles', and afterwards the opening of the College Buildings will take place. On Thursday, or on one or other of the specified days, there will be a graduation ceremonial, at which a number of honorary degrees will be conferred. On Thursday evening there will be a grand banquet, probably in the Corn Exchange ; on Friday afternoon a students' concert, and on the evening of that day a ball. It is not unlikely that in connection with the celebrations an illumination of the principal streets of the city will be recommended by the magistrates and council, though this has not been finally determined.

Calcutta Exhibition.—Messrs. W. A. Ross and Co., of Belfast, have been awarded two Gold Medals at the Calcutta Exhibition ; one for their Aërated Waters, and another for their Lime Juice. In addition to these they have received a Silver Medal for excellence in Cordials.

APPOINTMENTS.

Angus, J. A., M.R.C.S.—Medical Superintendent to the Hospital for Incurables, Newcastle-on-Tyne.

Baynes, James, jun.—Reappointed Analyst for one year, York (East Riding).

Daly, Charles A., L.R.C.S. Ire., L.K. & Q.C.P. Ire.—Medical Officer to the Houley District, Huddersfield Union.

Fairer, Matthew R., M.B., M.C. Edin.—Medical Officer to the Workhouse and the Kirkby Stephen District, East Ward Union.

Fitch, R.A., M.R.C.S., L.R.C.P.—Resident Surgeon to the Birmingham General Dispensary.

Gayton, William, L.R.C.P. Edin., M.R.C.S. Eng.—Medical Officer to the North-Western District Asylum, Metropolitan Asylum District.

Gibbes, H., M.D.—Lecturer on Morbid Histology in the Medical School of the Westminster Hospital.

Good, Fredk. T., M.R.C.S. Eng., L.S.A.—Medical Officer to the Second District, St. Neot's Union.

Gray, E. B., M.D., M.R.C.S.—Honorary Physician to the Radcliffe Infirmary, Oxford.

Hargreaves, J. B., F.R.C.S.—Consulting Surgeon to the Imperial Union Accidental Assurance Company for the Leeds District.

Hutchinson, John G., L.R.C.S. Edin., L.R.C.P. Edin.—Medical Officer to the Kineton District, Stratford-on-Avon Union.

Lane, W. A., M.S., Lond., F.R.C.S.—Assistant Surgeon to the Hospital for Sick Children, Great Ormond Street.

Maguire, Robert, M.D. Lond., M.R.C.P.—Pathologist to the Manchester Royal Infirmary, Demonstrator and Assistant Lecturer on Pathology in the Owens' College, Victoria University.

Salter, S. T., M.A., M.B.—House Surgeon to the Seamen's Hospital, Greenwich.

Simmons, H., L.S.A.—Assistant House Surgeon to the London Temperance Hospital, Hampstead Road.

Smith, James W., M.D., C.M., Edin.—Medical Officer to the Ryton District, Gateshead Union.

DEATHS.

Bushnan, J. S., M.D., &c., on February 17th, aged 76.

Carmichael, W., M.D., late Staff Surgeon R.N., at Mentone, on February 7th, aged 47.

Goldsbro', Charles Field, M.D., J.P., at Parnell, Auckland, New Zealand, on December 20th, 1883.

Hobbs, William, Surgeon Royal Navy (retired), at 6, Windsor-terrace, Douglas, on February 4th, aged 78.

Leslie, Armand, M.R.C.S., near Tokar, on February 4th.

VACANCIES.

Bedford General Infirmary and Fever Hospital. — Resident Surgeon. (*For particulars see Advertisement.*)

Bromsgrove Union, Romsley District.—Medical Officer. Area 4,366 acres. Population 686. Salary £12 per annum.

Chorlton Union.—Assistant Resident Medical Officer. Salary £120 per annum.

Queen Charlotte's Lying-in Hospital, St. Marylebone Road, W. —Resident Medical Officer. Candidates must be qualified, and have passed examination in Midwifery. The Appointment is for four months. Applications, with copies of testimonials, to be sent to the Secretary up to February 23.

Rochester and District Friendly Societies Medical Association.—Resident Medical Officer. Salary £200 per annum, &c. Candidates must be Fellows or Members of the Royal College of Surgeons of England, Edinburgh, or Dublin, and hold a Medical or Surgical Diploma, and be registered. Private practice prohibited. Applications, stating age, whether married or single, with testimonials, to be sent to H. T. Kybett, 55, High-street, Chatham, Kent, of whom further particulars may be obtained, on or before February 23.

Royal South London Dispensary, St. George's Cross, Lambeth Road, S.E.—Honorary District Surgeon. Applications to be sent to Mr. Hentsch, at the Dispensary, on or before February 29.

The General Hospital, Birmingham.—Resident Medical Officer. (*For particulars see Advertisement.*)

The Hospital for Women, Soho Square, W.—Assistant Physician. —Also, Administrator of Anæsthetics. (*For particulars see Advertisement.*)

Wonford House Hospital for the Insane, near Exeter.—Resident Medical Superintendent. Salary £500 a year, with furnished residence, board, washing, and attendance. Candidates must be registered both in Medicine and Surgery, and not less than 30 years of age. Applications, stating age, experience in the treatment of the insane, &c., whether married or single, with testimonials of recent date, to be addressed to the President, Committee of Management, Wonford House, Exeter, endorsed M.S., on or before March 11.

NOTES, QUERIES, AND REPLIES.

Royal College of Surgeons.—The following were the questions submitted to the nine candidates for the diploma in Dental Surgery, at a meeting of the Board on the 18th instant, when they were required to answer at least one of the two questions, both on Anatomy and Physiology, and on Surgery and Pathology, between two and four o'clock, p.m., viz. :—Anatomy and Physiology : 1. Give the precise attachments of all the Muscles connected with the Lower Jaw, exclusive of those of expression. 2. Mention the Nerves distributed to the Mouth, and state what you know respecting the functions attributed to each.—Surgery and Pathology : 1. Enumerate the several causes which prevent or hinder Movement of the Lower Jaw, and indicate the treatment you consider appropriate to each case. 2. Describe the Pathological and Clinical differences between an Epithelioma and an Epulis.

The following were the questions on Dental Anatomy and Physiology, and Dental Surgery and Pathology, in which the candidates were required to answer at least two of the three questions of each subject, viz. :—Dental Anatomy and Physiology : 1. Give the general Dental Formula of Marsupialia. Point out the leading resemblances and differences between their teeth and those of Placental Mammals, illustrating your answer by reference to an animal belonging to each class. 2. Describe the structure and development of Cementum, comparing it with Bone. What is its general distribution upon the teeth of Mammalia? 3. Name the periods of (i.) commencement of Calcification of the several Permanent Teeth, (ii.) of Eruption of the same, (iii.) (approximately) of completion of their Roots.—Dental Surgery and Pathology : 1. If during extraction a Tooth slip into the Throat, what complications may arise? what symptoms will denote its position? and what will be the appropriate treatment? 2. Mention the symptoms on which you would rely, and the tests you would employ in diagnosing Odontalgia from Neuralgia. 3. Describe the "transparent zone" of Dental Caries. What evidence exists as to its nature?

A young Licentiate.—The following gentlemen are members of the Dental Board of the College of Surgeons, according to the calendar of that institution :—Messrs. T. Holmes (Chairman), J. C. Forster, John Wood, F.R.S., Alfred Coleman, Augustus Winterbottom, and C. S. Tomes, F.R.S. All are Fellows of the College by examination, except the last-named gentleman, who is a Member. The Board was established in 1860, and was composed of Sir Wm. Lawrence, Bart., F.R.S. (as Chairman), and Messrs. J. H. Green, F.R.S., J. M. Arnott, F.R.S., Thomas Bell, F.R.S., John Tomes, F.R.S., and Arnold Rogers, F.R.C.S. ; with the exception of Messrs. Arnott and J. Tomes, all have gone over to the majority.

Senex.—We are grateful for your criticisms. We are well aware that the arrangement you complain of has its disadvantages, but we were not the first to introduce it into journalism, and we did not adopt it without due consideration.

Dr. R. L.—The article is not suitable for our pages.

X.P.—You will be able to get it through Williams and Norgate.

APPOINTMENTS FOR THE WEEK.

February 23. *Saturday* (*this day*).

Operations at King's College, 1 p.m.; St. Bartholomew's, 1½ p.m.; St. Thomas's, 1½ p.m.; London, 2 p.m.; Middlesex, 2 p.m.; Royal Free, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; Central London Ophthalmic, 2 p.m.

25. *Monday.*

Operations at the Metropolitan Free, 2 p.m.; St. Mark's Hospital for Diseases of the Rectum, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; Central London Ophthalmic, 2 p.m.; Hospital for Women, 2 p.m.; Royal Orthopædic, 2 p.m.

Medical Society of London.—Drs. Cayley, Samuel West, Gilbert Smith, A. T. Myers, and Mahomed, will read Papers embodying "The Results obtained in the London Hospitals by the Cold Bath Treatment of Enteric Fever."—Discussion.

Royal College of Surgeons of England, 4 p.m.—Prof. W. H Flower, LL.D., F.R.S., F.R.C.S., will deliver his First Lecture "On the Principal Types of the Human Species."

26. *Tuesday.*

Operations at Guy's 1½ p.m.; Westminster, 2 p.m.; West London, 2½ p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; Central London Ophthalmic 2 p.m.; Royal South London Ophthalmic 3 p.m.; St. Mark's Hospital, 9 a.m.

Royal Institution, 4 p.m.—Prof. A. Geikie, "Scenery of the British Isles."

Anthropological Institute of Great Britain and Ireland, 8 p.m.—The Institute will meet at 4, St. Martin's Place, W.C., when the following Papers will be read:—By the Rev. Lorimer Fison, M.A., "On the Nanga, or Sacred Stone Enclosure of Wainimala, Fiji;" by the Rev. R. H. Codrington, M.A., "On the Melanesian Languages."

Royal Medical and Chirurgical Society, 8.30 p.m.—Mr. Thomas F. Chavasse, "On Neurotomy of the Second Division of the Fifth Nerve;" Mr. Christopher Heath, "A Case of Amputation of the Arm and Scapula for Ossifying Sarcoma—Recovery." Dr. Heneage Gibbes, will show Microscopic Specimens of Putrefactive Organisms at 8 p.m.

27. *Wednesday.*

Operations at Middlesex, 1 p.m.; St. Mary's, 1½ p.m.; St. Thomas's, 1½ p.m.; St. Bartholomew's, 1½ p.m.; University College, 2 p.m.; London, 2 p.m.; Great Northern, 2 p.m.; King's College (ophthalmic operations), 1 p.m.; Samaritan, 2½ p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; Central London Ophthalmic, 2 p.m.; St. Peter's Hospital for Stone, 2 p.m.; National Orthopædic, Great Portland Street, 10 a.m.

Hunterian Society, 8 p.m.—Mr. R. Clement Lucas, "On Injuries to the Kidney;" Mr. Poland, "A case of Acute Suppuration of the Hip and Elbow Joints."

Royal College of Surgeons of England, 4 p.m.—Prof. W. H. Flower, LL.D., F.R.S., F.R.C.S., will deliver his Second Lecture "On the Principal Types of the Human Species."

28. *Thursday.*

Operations at St. George's, 1 p.m.; Central London Ophthalmic, 2 p.m.; University College, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal Westminster Ophthalmic, 1½ p.m.; Hospital for Diseases of the Throat, 2 p.m.; Hospital for Women, 2 p.m.; Charing Cross, 2 p.m.; London, 2 p.m.; North West London, 2½ p.m.

Parkes Museum of Hygiene, 8 p.m.—Dr. H. C. Bartlett, F.C.S., and Dr. Richard Neale will deliver Addresses "On the Purification of the Air in Living Rooms, Sick Wards, &c." Dr. B. W. Richardson, F.R.S., will take the Chair.

Royal Institution, 3 p.m. — Prof. Tyndall, "The Older Electricity."

29. *Friday.*

Operations at St. George's (ophthalmic operations), 1½ p.m.; Guy's 1½ p.m.; St. Thomas's (ophthalmic operations), 2 p.m.; King's College, 2 p.m.; Central London Ophthalmic, 2 p.m.; Royal London Ophthalmic, 11 a.m.; Royal South London Ophthalmic, 2 p.m.; Royal Westminster Ophthalmic, 1½ p.m.

Medical Society of Charing Cross Hospital, 8 p.m.—Meeting. H. Montague Murray, Esq., M.B., will read a Paper "On the Value of Phrenological Theories." Dr. J. Mitchell Bruce in the Chair.

Royal College of Surgeons of England, 4 p.m.—Prof. W. H. Flower, LL.D., F.R.S., F.R.C.S., will deliver his Third Lecture "On the Principal Types of the Human Species."

Royal Institution, 9 p.m.—Prof. Hughes, "Theory of Magnetism."

CLINICAL LECTURES

By J. MATTHEWS DUNCAN, M.D., F.R.S.,

Physician-accoucheur and Lecturer on Midwifery at St. Bartholomew's Hospital.

Lecture VII.—ON CHRONIC INVERSION OF THE UTERUS.

Inversion of the uterus is possible at any time, but is justly regarded as generally an accident of delivery at or near the full term. It is one of the most interesting and grave in the whole of midwifery practice, its importance being not of the greatest, only on account of its rarity. Its production and treatment, and many other matters concerning it, do not come into lectures on the diseases of women. But whether produced in the last stage of delivery, or in the unimpregnated female, it becomes a chronic disease if the woman survives and the organ is not replaced; and then it is truly one of the diseases of women, and we occasionally have a case in "Martha."

One point in its production should be considered here, namely, its occurrence without marked symptoms, or rather, without any special pain or constitutional disturbance. This is not usual; for generally it occurs in the third stage of labour or immediately after it, and then there is hæmorrhage and prostration, or collapse, great beyond all proportion to the amount of blood lost. The first case of recent inversion which I saw was one to which I was called some distance in the country; and, although I went at once, the patient was dead before my arrival, and had not had much loss of blood. The next case I saw was a case of chronic inversion, which we succeeded in replacing with great difficulty; it illustrates the point to which I now direct your attention. The patient was a doctor's wife, and she had the usual care and attention at her confinement, and all was supposed to go well. That inversion had taken place was not discovered till her child was a year old, and then accidentally, while enquiries were being made into her case, which was one of weakness, sacrache, and whites. Another case has come under my care, where the woman was supposed by her husband and friends to do very well in her confinement, while the doctor knew that the womb had become inverted. She made a good recovery, suckled her child, and long delayed applying to me to have her womb replaced. It was replaced, and she subsequently bore children. You are, therefore, not to suppose that this grand disease, associated in your minds with great sufferings, and consequences, has always grand symptoms at its beginning leading you to suspect its presence; it may occur without any, or with few and trifling symptoms, and little disturbance of health, at first or afterwards.

The symptoms of chronic inversion are sacrache,

leucorrhœal, or other discharges, and loss of blood, and these may vary in persistence and in amount. In a case not long ago in "Martha," the woman was very anæmic from great hæmorrhages, and in her the chronic inversion was peculiar, having been caused by a fibroid attached to the fundus, which had to be removed before the uterus was replaced. It is well worth your while to ponder the symptoms of chronic inversion and the consequences of it, when you study the subject of the so-called minor displacements. Here you have a most exaggerated form of displacement; but you have with it no such tremendous consequences as are attributed to the comparatively paltry versions and flexions. At the time of its production it is often truly an awful disease; but when it becomes chronic it loses this character, while it retains its own great though limited importance.

Another matter of great interest in the pathology of the uterus is the completeness of the involution, notwithstanding the inversion. In all the cases of chronic inversion which I have seen, the uterus was reduced to its natural size, and I have noticed it even remarkably small — not undersized, but small. It is a mobile, smooth, velvety-surfaced, rounded, pear-shaped mass, lying in the upper vagina, the small end of the pear being encircled by the cervix uteri. It is not tender, and, though sensitive, can be freely touched without the patient greatly complaining. The openings of the tubes have been seen on it, and they have been catheterised; but I have not been able to make them out in the cases that I have observed. All I have seen is a uniform bright and smooth surface, not necessarily bleeding when touched, but easily made to yield bloody oozing.

I have said that the inverted uterus hangs through the cervix. If the uterus is low down, or is pulled upon, then the cervix becomes inverted completely, even to the external os, and this leads me to an important matter which has practical bearings. The disease is essentially inversion, not of the uterus but of the body of the uterus. The body is quite a different organ from the cervix, and it is the inversion of the body that gives the disease all its important characters. There may be no inversion of the cervix; and if there is even complete inversion, it is of no moment; it can very easily be completely undone. It is, indeed, to be regretted that the cervix is made a part of the uterus, for this leads to many erroneous notions; it would be advantageous to have for it a different name, for it is physiologically and pathologically nearly as different from the uterus proper or uterine body above it, as it is from the vagina below it.

During the production of inversion, the uterus may be only partially displaced; and a partial inversion of the placental insertion, with a cup-like depression on the peritonæal surface may be felt in the third stage of labour; or a cup-like peritonæal depression may be seen on a womb which has expressed a polypus from its cavity into the cavity of the cervix or into the vagina. These are truly commencing inversions, not completed or real inversions. A chronic, partial, or not real inversion may be seen in some cases of continued hæmorrhage after delivery; the placental area being relaxed and projecting into the uterine cavity. But, disregarding the unimportant cervix, the displacement in a chronic uncomplicated inversion is always complete. I, at least, have not seen any partial inversion, and it is difficult to imagine a pathology for such a state.
